Original research

In vivo evaluation of microbial reduction after chemo-mechanical preparation of necrotic root canals with or without apical periodontitis

Ana Moura Teles, M. Conceição Manso, Cristina Pina, José Cabeda

ABSTRACT

Objectives: Assessment of bacterial reduction after chemo-mechanical preparation (using 3% sodium hypochlorite) with or without intracanal dressing (calcium hydroxide paste (Ca(OH)$_2$) or 2% chlorhexidine digluconate gel (CHX)) in necrotic pulps associated or not with apical lesion.

Methods: Prospective clinical trial, in 69 adult patient’s teeth with pulp necrosis associated or not with apical periodontitis. Microbiological root-canal-sampling occurred before treatment (S1), after chemo-mechanical preparation (S2) and after 14 days intracanal dressing (S3). Colony Forming Units (CFU) were counted after growth in aerobic, anaerobic and microaerophilic cultures. Comparison of the median CFUs treatments and culture media was done with the Friedman test. Comparison of the intracanal dressing effect at S3 was done with the Wilcoxon and the Mann–Whitney tests. Because of the huge differences in bacterial counts variations were expressed as log10 to analyze differences among intracanal medication groups. S2 and S3 counts were expressed as percentage of CFU reduction regarding S1 counts.

Results: Significant differences were detected between S1, S2 and S3 (Friedman test; $p<0.001$), showing a significant decrease from S1 to S2 (Wilcoxon test; $p<0.004$), followed by a significant increase from S2 to S3 ($p<0.001$) for the CHX group, maintenance for the Ca(OH)$_2$ group in aerobic/anaerobic (Wilcoxon test; $p=0.777/0.227$), and increase in the microaerophilic culture (Wilcoxon test; $p=0.047$). The two groups only differed significantly in S3 (Mann–Whitney test; $p<0.001$), with a worse performance in the CHX group.

Conclusions: Treatment significantly reduced the number of bacteria but failed to render all root canals sterile. Ca(OH)$_2$ performed better than CHX gel.
Avaliação da carga bacteriana após preparação químico-mecânica de dentes necrosados com ou sem lesão periapical

RESUMO

Objetivos: Avaliar a eficácia da preparação químico-mecânica com ou sem medicação intracanal (pasta de hidróxido de cálcio [Ca(OH)2] ou gel de digluconato de clorhexidina a 2% [CHX]) no tratamento de dentes necrosados com ou sem lesão periapical.

Métodos: Ensaios clínicos prospectivos em 69 dentes mononucleares com necrose pulpar ou periodontite apical. A colheita microbiológica ocorreu antes do tratamento (S1), após preparação químico-mecânica (S2) e após 14 dias de medicação intracanal (S3). Mediram-se as quantidades formadoras de colônias (UFC) em aerobiose, anaerobiose e microaerofilia. As medianas de UFC de diferentes tratamentos e culturas foram comparadas com o teste de Friedman. A comparação do efeito da medicação intracanal em S3 utilizou os testes Wilcoxon e Mann-Whitney. Dada a grande variabilidade de UFC nos diferentes momentos de colheita, as diferenças entre S1, S2 e S3 foram traduzidas em logaritmos de 10. As contagens de S2 e S3 foram expressas como percentagem de redução de carga bacteriana relativamente a S1.

Resultados: Encontraram-se diferenças significativas entre S1, S2 e S3 (testes Friedman; p < 0,001), com decréscimo significativo de S1 para S2 (teste Wilcoxon; p < 0,004), e aumento significativo de S2 para S3 (p < 0,001) no grupo de CHX, manutenção em aerobiose e anaerobiose (teste Wilcoxon; p = 0,777/0,227) e aumento em microaerofilia (teste Wilcoxon; p = 0,047) para o grupo experimental com Ca(OH)2. Os 2 grupos só diferiram significativamente em S3 (teste Mann-Whitney; p < 0,001), com pior desempenho da CHX.

Conclusões: O tratamento reduziu, de forma significativa, a carga bacteriana, mas não esterilizou os canais radiculares. O Ca(OH)2 apresentou melhor desempenho que a CHX.

Introduction

Apical periodontitis (AP) results from pulp space polymicrobial infection which, by symbiotic relationships, acquire specific sources of longer survival. Thus treatment must aim at all bacteria, microaerophilic, aerobic or anaerobic, strict or facultative, that is to say that the best scientific evidence-based documented procedure for the best outcome in endodontic treatment is based on the maximum disinfection of the root canal system.

Regardless of the number of sessions, an effective bacteriological control is mandatory. The biologic concerns should always be a priority.

Mechanical instrumentation coupled with sodium hypochlorite (NaOCl) irrigation dramatically reduces bacterial counts. However, since not all microorganisms are eliminated, intracanal dressing, primarily Calcium hydroxide paste (Ca(OH)2), has been advocated. Though, efficacy of this added step is controversial, both up to 97% bacterial reduction and increases in bacteria counts were reported. To overcome Ca(OH)2 limitations, 2% chlorhexidine digluconate gel (CHX) has emerged as an alternative. It has shown excellent antibacterial efficacy in vitro and a residual activity for up to 2 weeks or more. However, in vivo, liquid CHX resulted in bacterial load increase.

Treatment outcome may also be influenced by interindividual variability. This is even more evident when individuals from different geographical locations are analysed.

The present randomized clinical trial aimed at comparing the efficacy of chemomechanical cleaning alone and in combination with 2 intracanal dressings by 3 atmospheres of culture. To the best of our knowledge, this is the first report on the study of the microbiological microenvironment in root canals of Portuguese Patients.

Materials and methods

Study adhered to Helsinki Declaration. Protocol was approved by the Ethics Committee of health Sciences Faculty of Fernando Pessoa University and an informed consent was obtained.

Using stringent criteria as described by others, sample included 69 subjects (35 women/34 men; mean 49.7 years) with 69 single-teeth (18 central and 16 lateral maxillary incisors, 10 mandibular and 10 maxillary premolars, 9 maxilar and 6 mandibular canines). From those, 26 were only necrotic and 43 had AP. All were chemomechanically prepared and randomly divided into two groups: calcium hydroxide paste (Ca(OH)2) or 2% chlorhexidine digluconate gel (CHX). The random order of assignment was previously generated, using Excel-generated random numbers, which were concealed in opaque, sealed, serially numbered envelopes and applied to participants as they entered the trial. Ca(OH)2 (Sigma–Aldrich, Sintra, Portugal) was manufactured with sterile saline solution (SSS) and CHX was prepared by a private Pharmacy and maintained at

Samples in RTF vials were managed as described. Aliquots of 100 µL of undiluted and highest dilution (10⁻³) were spread onto BHI (Liofilchem Diagnostic, Italy) and Anaerobe Basal (Oxoid, United Kingdom) agar plates both supplemented with 5% defibrinated horse blood. Plates were incubated within jars, at 37 °C, anaerobically for 14 days and aerobically and microaerophilically (10% CO₂) for 48 h. Colony-Forming Units (CFUs) were then counted.

Statistical analysis was performed using IBM® SPSS® Statistics vs.20.0 (p < 0.05).

Differences among medication groups were calculated with log 10 transformations. S2 and S3 counts were expressed as percentage of CFU reduction regarding S1 counts (Table 1).

Differences in bacterial counts between S1, S2, and S3, among medication groups and initial diagnosis, were first analyzed with the Friedman test as non-normal distributions were always found (Shapiro–Wilks test). Upon detection of significant paired differences these were further investigated with the Wilcoxon test. Comparison of intracanal dressing effect at S3 was assessed using the Mann–Whitney test (Tables 2 and 3).

Results

Randomization of intracanal dressing proved to be independent of diagnosis (Chi-square test, p = 0.687), tooth position (p = 0.436) and “master apical file” (p = 0.233).

First appointment protocol succeeded in decreasing bacteria counts in all cases (p < 0.001), and in eliminating bacteria bellow detection level in 59 of 69 cases (85.5%). Results show a very efficient chemomechanical preparation demonstrated by the strong CFU reduction from S1 to S2 (Table 1): 97.2% (aerobiosis), 99.4% (microaerophilic atmosphere) and 98.5% (anaerobiosis), corresponding to 1.56, 2.24 and 1.83 log steps reduction, respectively (Wilcoxon test, p < 0.001 for all atmospheres).

A further reduction in positive samples from S2 to S3 was not always observed. After dressing with Ca(OH)₂, 70.6% of the canals (24 in 34) were negative for bacteria growth, whilst, in the CHX-group, only 28.6% (10 in 35 cases) proved negative. For CHX-group this resulted in a 70.3% CFU reduction for anaerobiosis (0.53 log step reduction), while Ca(OH)₂ showed over 5 log reduction, accounting for 100% reduction (Table 1).

A consistent significant CFU decrease between S1 and S2 (Wilcoxon test; p < 0.001) was found for both experimental groups (Table 2).

The same was not true for S2-S3 comparison: CHX-group showed a significant (p < 0.05) increase in all atmospheres; Ca(OH)₂ group showed similar counts in aerobiosis, and

4 °C till usage. All the irrigants and medicaments were always freshly prepared.

Sample collection was performed as previously described. Briefly, after rubber dam application, its disinfection was performed with 3% hydrogen peroxide, until no further bubbling followed by a 3% NaOCl rinse for 1 min as described. After access cavity, the operative field was disinfected as described above followed by inactivation of NaOCl with 5% sodium thiocyanate (Na₂S₂O₃). For operative field disinfection control, a sterile swab scanned in SSS was scrubbed on it and collected into tubes with 5 mL Phosphate Buffer Saline (Sample Sx). For inclusion of the tooth in the study, Sx samples had to be uniformly negative. S1 sample was acquired by placing three successive size 25 sterile paper points in the canal for 1 min each, approximately 1 mm short of the root apex and used to soak up the fluid in the canal and transferred into vials containing 2 mL sterile Reduced Transport Fluid (RTF). The working length (WL) was established with Root ZX apex locator (Morita, Kyoto, Japan) and confirmed by digital X-ray. Canals were enlarged with Protaper rotary instruments (Dentsply Maillefer, Ballaigues, Switzerland). File sequence used was: Sz until resistance was encountered, S1, S2, F₁, F₂, and F₃ at WL, according to each canal anatomy. Irrigation with 2 mL of 3% NaOCl was applied between consecutive files using a 27G needle (Endo needle, Elsodent, France) in an up-and-down motion to improve irrigant flow rate and a size 10K-file was used with WL + 1 mm (patency). In the cases of large canals, F₄ and F₅ files were used. After smear layer removal (5 mL 10% Citric Acid, 5 mL 3%NaOCl and 5 mL 5%Na₂S₂O₃), S2 sample was acquired. After drying, intracanal dressings were applied using lentulo spiral fillers with clockwise motion without water rinse and packed with a sterile cotton pellet at the canal entrance level. Another sterile cotton pellet input plug was placed and teeth were sealed with Coltostol (Coltène/Whaledent Inc., USA) for 14 days.

At the second appointment, after evaluation of the integrity of temporary restoration, restoration removal and similar field disinfection, another Sz was retrieved as described. Then, intracanal dressing was removed with 5 mL SSS for the Ca(OH)₂-group and Lecitin, Tween 80 and Na₂S₂O₃ solution for the CHX-group. Dressing removal was confirmed with a Carl Zeiss® Microscope, and S3 samples (to assess medicament’ efficacy) were then collected as described for S1 and S2. After a final rinse, filling seated to gutta-percha points and TopSeal (Dentsply, Maillefer, Ballaigues, Switzerland), the canal entrance was sealed with Synergy D6 Flow (Coltène/Whaledent, USA) and access cavity temporized.
Table 2 – Effect of endodontic procedures on bacteria (CFU/mL) for both intracanalar dressings (CHX and Ca(OH)₂), sampling moments (S1, S2 and S3) and the three atmospheres.

* Friedman test; a, b, c – different letters stand for significant differences (median) between collection sampling moments, according to the Wilcoxon test; A, B – different letters stand for significant differences (median) between intracanalar dressings (at S3), according to the Mann–Whitney test.
significantly ($p < 0.05$) increased counts in microaerophilic and anaerobic atmospheres (Table 2).

Comparison of CFU counts at similar sampling moments between the groups showed that significant differences were only observed in S3 (Mann–Whitney test; $p < 0.001$), with a worst performance of CHX (Table 2).

Next, CFU counts were compared according to the initial diagnosis (Table 3): in teeth presenting only necrosis, neither intracanal dressings showed significant CFU reduction between S1 and S3 or S2 and S3. However, those presenting AP showed a significant reduction between S1 and S3 when treated with Ca(OH)$_2$ ($p < 0.033$ for all atmospheres) and a maintenance of low CFU counts between S2 and S3 ($p > 0.05$), while CHX shows a significant increase between S2 and S3 ($p < 0.002$ for all atmospheres).

Thus, comparison at S3 shows significantly lower values in Ca(OH)$_2$ than in CHX-group (Mann–Whitney test; $p < 0.002$ for all atmospheres), a fact even clearer with AP diagnosis.

### Discussion

AP is caused by a habitat-adapted polymicrobial infection of the pulp space. The microbial flora typically consists of a restricted group of species, dominated by pigmented Gram-negative anaerobes with fastidious environmental and nutritional requirements.\(^{1,2}\)

There is a current trend to include AP in the category of biofilm-induced diseases which is a major step forward to the understanding of root canal infection.\(^{25–28}\)

Culture medium was used because of its ability to detect exclusively viable bacteria and the correlation shown by previous studies between negative cultures and a more favorable treatment outcome.\(^{18,26}\)

In order for microorganisms to multiply in artificial media, they must have available the required nutrients and proper physicochemical conditions, including temperature,
moisture, atmosphere, salt concentration and pH. Thus, given the poly-microbial nature of the endodontic micro flora and the fact that a synergetic balance is required for the survival of strict anaerobes in the presence of other aerobic and facultative anaerobes, it can be suggested that growth of bacteria in enriched broth media in different atmospheres may be more suitable because it may allow detection of even the less frequent bacteria species in the canal. These were the reasons for using a more laborious laboratory protocols (3 different atmospheres) than other reports in this field that only assessed anaerobic culture. 

The 14-days anaerobic atmosphere culture results were used, in contrast with the aerobic and microaerophilic atmospheres where 48 h were sufficient to assess bacterial growth. Clinicians may consider chemomechanical cleaning and shaping of the root canal system as total disruption of the endodontic microbial ecosystem. Our data are in total agreement with previous reports that have repeatedly demonstrated significant bacteria reductions with chemomechanical instrumentation and that waiting for treatment completion at a later date results in higher bacterial counts. Nevertheless, similar to other reports, the present results clearly showed that cleaning and shaping alone were insufficient to produce a sterile root canal.

Intracanal dressings also failed to render all root canals sterile. This was particularly true in the CHX-group. This could result from a number of reasons: (a) presence of bacteria in sampling inaccessible areas; (b) a flaw during S2 sample collection; (c) contamination during introduction of the intracanal drug; (d) persisting bacteria either intrinsically resistant to drug or protected from the medicaments by biofilms; (e) inactivation of medicament by compounds in pulp space.

CHX activity is pH dependent and is greatly reduced by dentin, inflammatory exudates, bacterial products, or the necrotic tissue. This could explain the reversal growth in 25 cases, which is in accordance with a previous report. Our results suggest that CHX has a limited effect as intracanal medication for 2 weeks in vivo.

The percentage of Ca(OH)2 related positive cultures observed in this study was within the range reported in previous studies. The reported variation of Ca(OH)2 effectiveness may be explained by a large variety of factors including: tooth-type, initial microbial loading, operator-associated variables, instrumentation technique, irrigants, elimination of smear layer, integrity of temporary restorations, and geographic differences of endodontic infectious bacteria.

Immunological response to pulpal necrosis and AP is different, and this may explain the dissimilar performance of the Ca(OH)2 in these two clinical conditions. In fact, despite its well-known antimicrobial activity, Ca(OH)2 actions far exceed it. It is known to inactivate endotoxins, stimulate mineralization, dissolve organic material, and produce a chemical and physical barrier. Its immunoregulator properties were demonstrated in an in vitro study, where Ca(OH)2 either reduced cytokine basal expression or prevented increase of all cytokines tested during the experimental period. Another possibility is that persistent Ca(OH)2 in root canals can denote Interleukin-1α, Tumor Necrosis Factor-α, and calcitonin gene-related peptide suggesting a dampening effect of Ca(OH)2 in periapical inflammation after root canal cleaning procedures. Thus differences observed in Ca(OH)2 performance between necrotic and AP teeth may also be related to differential activities of the drug in the presence of different basal immunological involvements.

Conclusion

From a microbiological point of view, treatment of necrotic teeth with intracanal dressing to render root canals bacteria-free before filling seems to be questionable. Nevertheless, the present results indicate that if this strategy is used, Ca(OH)2 should be preferred to CHX. Results also indicate that if a two session protocol with intracanal dressings is chosen, removal of residual canal flora by chemomechanical cleaning at the second visit is mandatory.
