Abstract
Background: Primary angioplasty improves outcomes of acute myocardial infarction (AMI). However, in the highest risk subgroups, the mortality remains high despite modern catheter-based reperfusion therapy. This study analyzed patients with AMI caused by the left main coronary artery unstable lesion, a subgroup considered to be associated with very high early mortality.

Methods: A multicenter registry enrolled 6742 consecutive patients with AMI. Ninety-seven patients (1.4% of the entire study population) had left main as the infarct related artery. Baseline clinical characteristics, ECG patterns, coronary angiographic and echocardiographic data were correlated with the revascularization therapies used and with in-hospital outcomes.

Results: Twenty-five patients (25.8%) died during the hospital stay. The deceased patients were older, had more frequently bundle branch block on the admission ECG, had higher Killip class on presentation, more frequently had TIMI flow 0–2 and PCI success rate was 72% (vs. 100% among survivors). Left main coronary artery (LMCA) lesion impaired distal flow (TIMI flow 0–2 on presentation) in 35 patients: the most frequent ECG presentation pattern for these LMCA occlusions was ST segment elevation (n = 17), followed by RBBB (n = 9; with LAH 6 and without LAH 3), LBBB (n = 6) and ST segment depression (n = 3). In other words: acute LMCA occlusion presents in 51% with ECG changes other than ST segment elevations. Patients with TIMI flow 0–2 had higher Killip class on admission, lower ejection fraction and higher in-hospital mortality (37% vs. 20%), when compared to those with TIMI flow 3 on the initial angiogram.

Conclusions: Despite modern interventional therapy, acute myocardial infarction caused by the left main coronary artery obstruction bears high early mortality. The presence of bundle branch block, diminished TIMI flow on the initial angiogram, higher age and Killip class are related with increased mortality.

1. Introduction

Primary percutaneous coronary intervention (PCI) improves outcomes of acute myocardial infarction (AMI) when compared to thrombolytic therapy [1–3]. However, in the highest risk subgroups, the mortality remains high despite modern catheter-based reperfusion therapy. These subgroups include elderly patients, patients with signs of acute heart failure (Killip II–IV class on admission [4]) and patients with critical coronary angiographic findings (left main coronary artery occlusion, last remaining artery occlusion, occlusion of the artery supplying the last viable region of the left ventricle, etc.). This study analyzed one of these high risk subgroups—patients with AMI caused by the left main coronary artery acute occlusion or unstable critical stenosis.

2. Methods

2.1. Patient population

A multicenter registry enrolled 6742 consecutive patients with AMI, who were admitted to one of the seven participating hospitals during a 3 years period. Ninety-seven patients (1,4% of the entire study population) had left main as the infarct related artery. Baseline clinical characteristics are in Table 1.

2.2. Electrocardiographic (ECG) patterns

Upon admission were registered and assigned into one of the following categories: LBBB, RBBB (± LAH or LPH), ST segment elevation, ST segment depression, other ECG pattern.

2.3. Coronary angiographic data

Included the infarct related artery (as assigned by the interventional cardiologist, who performed the procedure), TIMI flow grade before and after PCI, number of major epicardial arteries with >50% stenosis and the result of PCI procedure. Ejection fraction was registered by echocardiography.

All these findings were correlated with the revascularization therapies used (PCI, CABG or thrombolysis) and with in-hospital mortality.

2.4. Statistical analysis

For continuous variables, mean values and standard deviations were calculated. After checking normality by the Shapiro–Wilk test, Student’s two-sample t-test was used for testing of the hypotheses about the means in compared groups. Satterthwaite’s correction for unequal variances was applied where appropriate. Mann–Whitney test was used for the ordinal variables (e.g. Killip class). Categorical data were tested with Fisher’s exact test and Pearson’s χ² test. All tests have been performed as two-sided on the level of significance 0.05. Statistical software Stata, release 9.2 (Stata Corp LP, College Station, TX) was used for the analysis.

3. Results

3.1. Overall mortality among all LMCA—AMI patients

Twenty-five out of the 97 patients (25,8%) died during the hospital stay. The deceased patients were older, had more frequently bundle branch block on the admission ECG, had higher Killip class on presentation, more frequently had TIMI flow <3 and PCI success rate was 72% (vs. 100% among survivors—see Table 2).
3.2. **ECG in the subgroup with LMCA functional occlusion**

Left main coronary artery (LMCA) was functionally occluded (TIMI flow 0–2 on presentation) in 35 patients: the most frequent ECG presentation pattern for LMCA occlusion was ST segment elevation ($n = 17$), followed by RBBB ($n = 9$; with LAH 6 and without LAH 3), LBBB ($n = 6$) and ST segment depression ($n = 3$). In other words: acute LMCA occlusion presents in 51% with ECG changes other than just ST segment elevations (Fig. 1). Patients with LMCA functional occlusion (vs. those with initial TIMI-3 flow) had higher Killip class on admission, lower ejection fraction and higher in-hospital mortality (37% vs. 20%) when compared to those with TIMI 3 flow on the initial angiogram (Fig. 2, Table 3).

4. Discussion

4.1. Survival predictors

The main predictors of survival were lower age, lower Killip class on admission and preserved TIMI 3 flow on the initial coronary angiogram. These variables have been shown to predict survival also in other AMI patients [4]. Patients with LMCA critical unstable lesion and TIMI flow <3 frequently present to the hospital in advanced cardiogenic shock, in pulmonary edema or after resuscitation and thus emergent restoration of the LMCA patency is crucial to keep at least some chance for survival.

4.2. Electrocardiographic signs of LMCA acute occlusion

Terkelsen et al. [5] analyzed mortality from acute myocardial infarction in a defined region of Denmark with known population and full coverage of mortality data. They found, that bundle branch block (and especially RBBB) during acute myocardial infarction is related with the highest mortality among all electrocardiographic types of infarction. Similar observations were published by others [6–14]. Hirano et al. [10] found, that 37% of patients with acute myocardial infarction caused by the left main coronary artery occlusion present with RBBB, while only 3% with LBBB. We have shown, that acute LMCA occlusion presents in 26% only with RBBB, without ST segment elevations being in close accordance both to previously mentioned reports and with Hirano et al., who found, that in 30% of left main coronary artery occlusions no ST segment elevation could be found on the admission ECG, while RBBB with left axis deviation (frequently accompanied by ST-elevation in aVR) is typical for this catastrophic type of AMI. The study by Kurisu et al. [11] found RBBB even in 52% of patients with acute occlusion of the left main coronary artery.

4.3. Revascularization procedures

The guidelines of the European Society of Cardiology (ESC) list only LBBB as an indication for urgent reperfusion therapy [15]. The American Heart Association (AHA)/American College of Cardiology (ACC) guidelines provide similar recommendations [16]. Our recent study [17] suggested, that RBBB should be listed in the guidelines as an indication for emergent reperfusion therapy, preferably by means of PCI.

4.4. Study limitations

This is not a randomized study, but just a multicenter “real-life” registry. Coronary angiography was not evaluated in an independent core laboratory. This fact may bear inherent risk of interindividual differences in TIMI flow and PCI success evaluation. Moreover, detailed hemodynamic data on admission are not available. However, such a critical setting as LMCA occlusion or preocclusion requires immediate therapeutic intervention and advanced hemodynamic description is not feasible.

5. Conclusions

Despite modern interventional therapy, acute myocardial infarction caused by the left main coronary artery obstruction has high early mortality. The presence of bundle branch block, diminished TIMI flow on the initial angiogram, age and Killip class are related with increased mortality.
