SUMMARY

The hair follicle bulge in the epidermis associates with the arrector pili muscle (APM) that is responsible for piloerection (“goosebumps”). We show that stem cells in the bulge deposit nephronectin into the underlying basement membrane, thus regulating the adhesion of mesenchymal cells expressing the nephronectin receptor, $\alpha 8\beta 1$ integrin, to the bulge. Nephronectin induces $\alpha 8$ integrin-positive mesenchymal cells to upregulate smooth muscle markers. In nephronectin knockout mice, fewer arrector pili muscles form in the skin, and they attach to the follicle above the bulge, where there is compensatory upregulation of the nephronectin family member EGFL6. Deletion of $\alpha 8$ integrin also abolishes selective APM anchorage to the bulge. Nephronectin is a Wnt target; epidermal β -catenin activation upregulates epidermal nephronectin and dermal $\alpha 8$ integrin expression. Thus, bulge stem cells, via nephronectin expression, create a smooth muscle cell niche and act as tendon cells for the APM. Our results reveal a functional role for basement membrane heterogeneity in tissue patterning.

INTRODUCTION

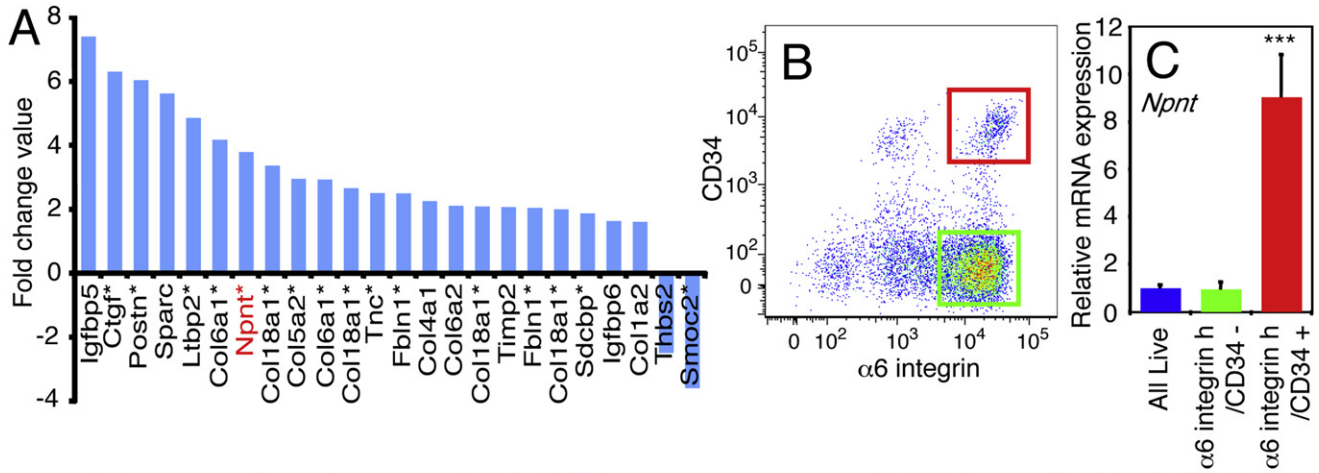

The epidermis is maintained through self-renewal of stem cells and differentiation of their progeny to form the lineages of the interfollicular epidermis and adnexal structures, including the hair follicles and sebaceous glands (Watt et al., 2006). There are several distinct populations of stem cells in adult epidermis. Their properties are regulated by intrinsic transcriptional programs in response to signals from the external microenvironment, or niche (Watt and Hogan, 2000; Watt et al., 2006).

One location of epidermal stem cells is the permanent portion of the hair follicle, known as the bulge. During the resting phase

of the hair growth cycle (telogen), bulge cells are in close contact with a cluster of mesenchymal cells known as the dermal papilla, and reciprocal interactions between epidermal stem cells and dermal papilla cells are essential for hair follicle formation and maintenance (Millar, 2002; Yang and Cotsarelis, 2010). A second close association between the bulge and the adjacent mesenchyme involves a smooth muscle called the arrector pili muscle (APM), which is responsible for raising the hair follicles (piloerection) to trap body heat and express emotions. Unlike the association between the bulge and the dermal papilla, which is lost during the growth (anagen) phase of the hair growth cycle, the bulge maintains contact with the APM throughout the hair cycle (Müller-Röver et al., 2001). Although it is well known that the bulge is the permanent attachment site of the APM, how attachment of the muscle is established and maintained in the bulge is entirely unknown.

We hypothesized that bulge-arrector pili muscle interactions might involve epidermal basement membrane components. Laminin-511 has been shown to mediate epidermal-dermal papilla signaling during hair development (Gao et al., 2008), and in a range of other tissues, such as kidney and pancreas, the basement membrane is involved in bidirectional cellular interactions (Linton et al., 2007; Nikolova et al., 2006). Furthermore, the basement membrane of the skin exhibits local variation in structure and composition (Timpl, 1996). Such basement membrane heterogeneity would not only provide a potential mechanism for anchoring different stem cell populations in different regions of the epidermis, but could also result in local differences in signaling with adjacent mesenchymal cells (Akiyama et al., 1995; Fuchs, 2008; Spradling et al., 2001; Watt and Hogan, 2000).

Gene expression profiling of the bulge compartment has revealed that bulge stem cells express a number of extracellular matrix (ECM) proteins that are distinct from those of other epidermal cells (Morris et al., 2004; Ohyama et al., 2006; Tumber et al., 2004). One of these is nephronectin, an ECM protein with five EGF-like repeats, an RGD sequence, and a COOH-terminal MAM domain (Brandenberger et al., 2001). Nephronectin is an interesting candidate mediator of epidermal interactions with mesenchymal cells because the nephronectin receptor is $\alpha 8\beta 1$

(Brandenberger et al., 2001; Sato et al., 2009), an integrin that is expressed in the dermal papilla, but not by adult epidermal keratinocytes (Driskell et al., 2009; Watt, 2002). Furthermore, the epithelial-mesenchymal interactions that are required for kidney organogenesis are disrupted in mice lacking $\alpha 8\beta 1$ or nephronectin (Brandenberger et al., 2001; Linton et al., 2007; Müller et al., 1997).

In this study, we show that bulge stem cells create a specialized basement membrane containing nephronectin, which induces arrector pili muscle differentiation and anchorage to the bulge. Loss of nephronectin or $\alpha 8$ integrin expression causes delocalization of the APM. Thus, the bulge ECM not only contributes to the specialized niche of hair follicle stem cells, but also provides a niche for smooth muscle progenitors.

RESULTS

Bulge Stem Cells Deposit Nephronectin

By examining published microarray data, we identified a range of ECM genes that were upregulated in bulge stem cells, including nephronectin (*Npnt*) (Figure 1A and Tables S1–S3 available online). To confirm that nephronectin was upregulated in bulge cells, Q-PCR was performed on mRNA from disaggregated dorsal skin keratinocytes that had been FACS sorted on the basis of the expression of bulge stem cell markers CD34 and $\alpha 6$ integrin (Figure 1B). CD34+/ $\alpha 6$ integrin^{high} cells were enriched for expression of the additional bulge maker *Sox9* and expressed low levels of *Sca1*, a marker of interfollicular epidermal cells (Figure S1A) (Jensen et al., 2009; Trempus et al., 2003). These cells had high levels of *Npnt* in comparison with unfractionated basal cells (all live; cells with low forward and side scatter) and CD34-/ $\alpha 6$ integrin^{high} nonbulge stem cells (Figure 1C). Expression levels of other ECM genes identified from the microarrays were also confirmed by Q-PCR (Figure 1A and Figure S1A).

We next examined the distribution of nephronectin protein in embryonic and adult skin. At E14.5, nephronectin was detected throughout the epidermal-dermal basement membrane, where it was colocalized with the ubiquitous basement membrane component laminin $\gamma 1$ chain (Figure 1D and Figure S1B). However, at E16.5 and E18.5, when hair follicle morphogenesis had begun, nephronectin accumulated between the hair germ and dermal condensate but was hardly detectable along the rest of the hair follicle (Figures 1E and 1F and Figure S1B). Just after birth (P1, P5), nephronectin was detected in the basement membrane of keratin 15 (K15)- and *Sox9*-positive early bulge stem cells as well as at the base of the follicle (Figure 1G and

Figures S1B and S1C). At this time, nephronectin deposition in the bulge was asymmetrically distributed at the posterior side (Figures 1G and 1H and Figure S1B).

In adult telogen and anagen skin, nephronectin was localized to the basement membrane of the bulge, hair bulb, and APM (Figures 1I and 1J and Figure S1B). Other ECM proteins that localized to the bulge rather than along the entire outer root sheath were periostin and fibulin-1 (Figure S1D). Tenascin-C was confined to the bulge in telogen follicles but showed more widespread distribution in anagen (Figure S1D).

In situ hybridization for *Npnt* mRNA in embryonic and adult skin confirmed that nephronectin is expressed by epidermal cells. Epithelial cells of the bulge and hair germ were strongly positive for *Npnt* mRNA, whereas the dermis was negative (Figures 1K–1M). We conclude that expression of nephronectin by bulge stem cells and hair germ cells results in heterogeneity in epidermal basement membrane composition from early hair morphogenesis to adulthood.

$\alpha 8$ Integrin Is Specifically Expressed by Cells of the Dermal Papilla and Arrector Pili Muscle and Colocalizes with Nephronectin

Because $\alpha 8\beta 1$ integrin is the major nephronectin receptor (Brandenberger et al., 2001; Sato et al., 2009), we examined whether $\alpha 8\beta 1$ integrin colocalized with nephronectin in embryonic and adult skin. Whole-mount immunostaining of E14.5 dorsal skin revealed that $\alpha 8$ integrin was strongly expressed in dermal condensates (arrowheads in Figure 2A) and also widely expressed in the superficial dermis, correlating with the widespread distribution of nephronectin in the basement membrane (arrows in Figure 2A). Between E16.5 and E18.5, $\alpha 8$ integrin expression in the superficial dermis was downregulated, but it was highly expressed in the dermal condensates and dermal papillae of developing hair follicles and colocalized with nephronectin (arrowheads in Figures 2B and 2C).

At P1 and P5, $\alpha 8$ integrin-positive dermal cell clusters were detected in association with nephronectin in the early bulge (open arrowheads in Figures 2D and 2E) and elongated toward the interfollicular epidermis (Figure 2E), whereas $\alpha 8$ integrin was downregulated in dermal papillae of hair follicles in late anagen (Figures 2D and 2E). In adult telogen skin, $\alpha 8$ integrin accumulated at the interface between hair germ and dermal papilla, colocalizing with nephronectin (arrow in Figure 2F). The arrector pili muscles coexpressed $\alpha 8$ integrin and nephronectin and inserted into the nephronectin-positive bulge (Figure 2F). In addition to nephronectin, $\alpha 8\beta 1$ binds to several ECM proteins,

Figure 1. Nephronectin Expression in Skin

(A) ECM genes that are upregulated or downregulated in bulge stem cells relative to other basal keratinocytes, ranked based on \log_2 fold change value (see Table S1). Asterisks indicate the genes that are also upregulated or downregulated in mouse label retaining cells (Tables S2–S3). Some genes are listed more than once due to their multiple spots on the array.

(B and C) Adult telogen dorsal keratinocytes were FACS sorted according to $\alpha 6$ integrin and CD34 expression (B). Bulge stem cells (red gate; $\alpha 6$ integrin^{high}/CD34+), nonbulge basal stem cells (green gate; $\alpha 6$ integrin^{high}/CD34-), and all live basal cells were sorted, and *Npnt* mRNA levels were determined by Q-PCR (C). Data are mean \pm SEM from three mice.

(D–J) Sections of E14.5 (D), E16.5 (E), E18.5 (F), P1 (G), P5 (H), adult telogen (I), and anagen (J) skin were immunostained for nephronectin (NPNT; green) and bulge stem cell marker K15 (red), with DAPI counterstain (blue). Note nephronectin deposition in hair germ (white arrowheads), bulge (open arrowheads), and APM (arrows).

(K–M) In situ hybridization with *Npnt* probe on E16.5 (K), P1 (L), and adult telogen skin (M). Arrows indicate strong nephronectin expression. Scale bars, 50 μ m. See also Figure S1 and Tables S1–S3.

including osteopontin, tenascin-C, fibronectin, and vitronectin (Brandenberger et al., 2001; Denda et al., 1998; Schnapp et al., 1995). However, none of these proteins showed specific colocalization with $\alpha 8$ integrin (Figures S2A–S2D).

To identify the $\alpha 8$ integrin-positive cells associated with the early bulge cells, we stained newborn skin sections with a panel of antibodies. At P1, the $\alpha 8$ integrin-positive population expressed dermal fibroblast markers PDGFR α and HSP47 (Figure 2G and Figure S2E) (Erez et al., 2010; Kuroda and Tajima, 2004). $\alpha 8$ integrin-positive cells in the dermal papilla expressed CD133 (white arrowhead in Figure 2H) (Driskell et al., 2009), but CD133 was not expressed by $\alpha 8$ integrin-positive cells at the bulge (open arrowhead in Figure 2H). $\alpha 8$ integrin-positive cells did not express the endothelial cell marker CD31, the neural crest cell derivative marker nestin, or the neuron-specific marker β III tubulin (Figures 2I–2L). At P1, bulge-associated $\alpha 8$ integrin-positive cells did not express smooth muscle actin α -SMA (Figure 2M). However, from P5 onward, they were strongly positive for α -SMA (Figures 2N and 2O) and dystrophin (Figure S2F). These results suggest that the $\alpha 8$ integrin-positive fibroblasts associated with the bulge in P1 skin are progenitors of the APM.

$\alpha 8$ Integrin-Positive Dermal Cells Adhere Strongly to Nephronectin and Upregulate Smooth Muscle Markers

The specific colocalization of nephronectin and $\alpha 8$ integrin led us to hypothesize that nephronectin mediates adhesion of $\alpha 8$ integrin-positive dermal cells to the bulge basement membrane. To examine this, we performed solid-phase cell adhesion assays with purified nephronectin. Disaggregated P1 dorsal dermal cells were sorted on the basis of surface $\alpha 8$ integrin expression (Figure 3A). Q-PCR analysis confirmed that $\alpha 8$ integrin mRNA (*Itga8*) was upregulated in the $\alpha 8^{\text{high}}$ population, whereas cells with high or low $\alpha 8$ integrin levels showed little variation in $\beta 1$ integrin (*Itgb1*) levels (Figure 3B). Solid-phase cell adhesion assays revealed that $\alpha 8$ integrin^{high} dermal cells adhered strongly to nephronectin-coated substrates in a concentration-dependent manner, whereas $\alpha 8$ integrin^{low} dermal cells did not (Figures 3C and 3D). In contrast, both populations adhered equally well to laminin-coated substrates (Figures 3C and 3D).

Unfractionated, $\alpha 8^{\text{high}}$ and $\alpha 8^{\text{low}}$ cells were plated on nephronectin, laminin, or a mixture of both for 12 hr and then collected for Q-PCR analysis (Figure 3E). We examined expression of two smooth muscle cell marker genes, α -smooth muscle actin (α -SMA; *Acta2*) and smooth muscle protein 22- α (*Sm22a*), and two dermal papilla cell marker genes, *Cd133* and *Corin*. Prior to plating, $\alpha 8^{\text{high}}$ cells expressed high levels of *Cd133* and *Corin*, consistent with their presence in dermal papillae (Figure 3E). However, expression of these markers was downregulated, regardless of whether the cells were plated on nephronectin or

laminin (Figure 3E). In contrast, the $\alpha 8$ integrin^{high} population showed significant upregulation of *Acta2* and *Sm22a* when plated on nephronectin or nephronectin and laminin, but not on laminin alone (Figure 3E).

We conclude that nephronectin mediates adhesion of $\alpha 8$ integrin-positive dermal cells and stimulates expression of APM markers.

Nephronectin Is Required to Anchor Arrector Pili Muscles to the Bulge

To investigate the function of nephronectin in vivo, we analyzed *Npnt* knockout mice (Linton et al., 2007). Analysis of hematoxylin and eosin (H&E)-stained sections of adult dorsal telogen skin did not reveal any gross abnormalities, and there was no significant difference in the size of hair bulbs and dermal papillae (Figures 4A and 4B and data not shown). However, in *Npnt*^{-/-} skin, $\alpha 8$ integrin was absent from the basement membrane separating the dermal papilla and hair germ and was more prominently distributed at the periphery of the dermal papilla (Figures S3A–S3C). The effect was specific to $\alpha 8$ integrin because the distribution of the phylogenetically related RGD-binding integrin subunits, $\alpha \nu$ and $\alpha 5$, in dermal papillae was not altered (Figures S3D and S3E). In addition, lack of nephronectin did not affect the distribution of the ubiquitous basement membrane component, laminin $\gamma 1$ chain (Figure S3B).

To examine whether loss of nephronectin affected the APM, we stained sections of adult telogen dorsal skin with anti- α -SMA. In control skin, muscles were detected in association with 95.9% \pm 1.2% of hair follicles. In *Npnt*^{-/-} skin, there was a small but significant decrease in the percentage of hair follicles with arrector pili muscles (82.2% \pm 3.3%) (Figures 4C–4E).

Given the obvious limitations of conventional histology for analyzing the spatial relationship between the APM and the hair follicle, we developed a whole-mount labeling technique in which we could observe the interaction in three dimensions. Arrector pili muscles were visualized by staining for α -SMA and SM22 α , and hair follicles were visualized by DAPI labeling or Keratin 14 (K14) staining. There was an inverse gradient of α -SMA and SM22 α , with α -SMA being more abundant next to the bulge and SM22 α closer to the interfollicular epidermis (Figure 4F and Figure S3F). Individual muscle bundles usually branched to insert into the bulges of several neighboring hair follicles, and each follicle typically had one associated muscle bundle (Figure 4F).

Using whole-mount visualization, we confirmed the reduced number of hair follicles with associated arrector pili muscles in *Npnt*^{-/-} skin: 99.7% of control follicles had an associated muscle, compared with 93.3% in knockout skin (Figures 4G–4I). There was also a significant reduction in the number of muscle attachment sites per hair follicle (Figure 4J). However,

(White arrowhead in G and H) Dermal papilla. All sections were counterstained with DAPI (blue). Asterisk indicates nonspecific staining. Scale bars, 50 μ m. See also Figure S2.

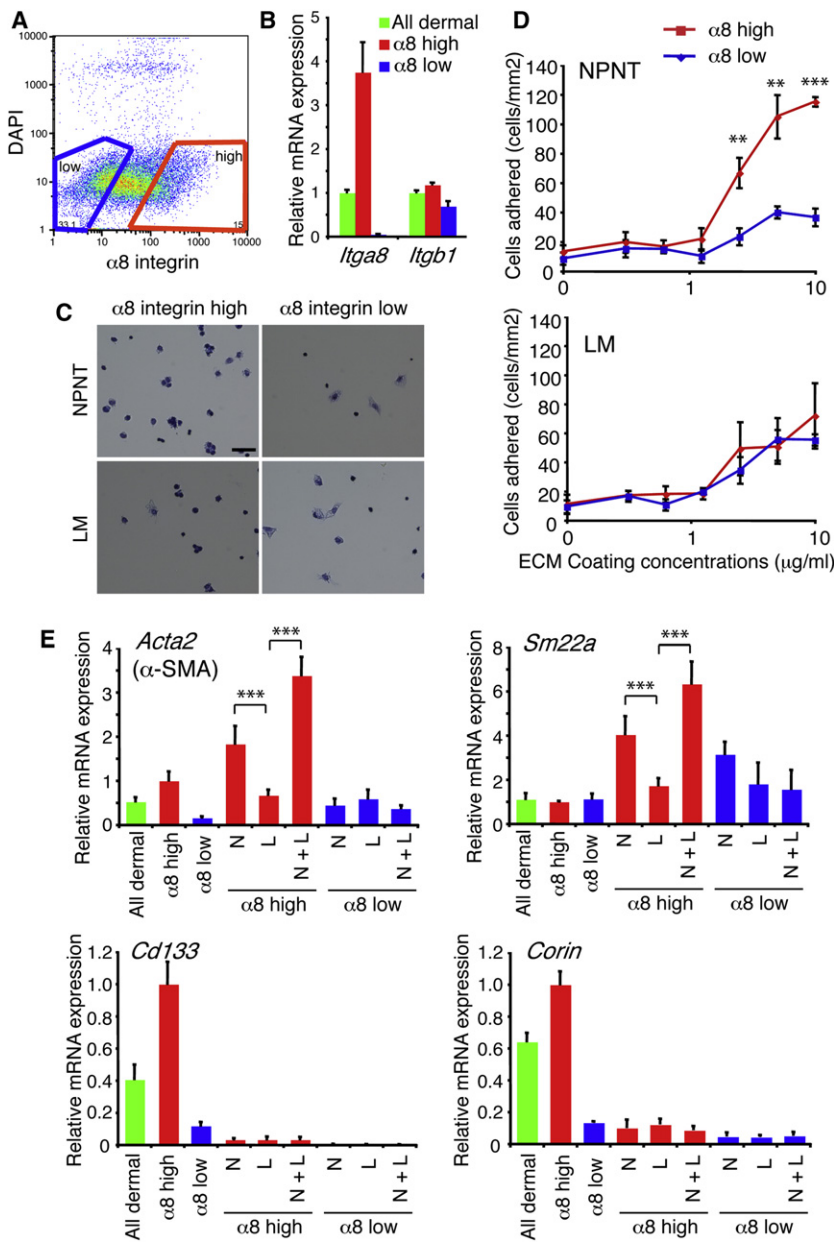

Figure 3. Adhesion and Gene Expression of Dermal Cells Plated on Nephronectin

(A and B) Disaggregated P1 dermal cells were FACS sorted on the basis of $\alpha 8$ integrin levels (A), and $\alpha 8$ integrin (*Itga8*) and $\beta 1$ integrin (*Itgb1*) expression was confirmed by Q-PCR. (B). Data are means \pm SEM from three mice.

(C and D) Solid-phase cell adhesion assays with FACS-sorted dermal cells plated on nephronectin (NPNT)- or laminin (LM)-coated dishes (10 μ g/ml). Cells were stained with Diff Quik (C) and quantitated (D). (C) Scale bar, 50 μ m. (D) Data are means \pm SEM from triplicate wells.

(E) Q-PCR of smooth muscle (*Acta2* and *Sm22a*) and dermal papilla marker (*Cd133* and *Corin*) expression in unfractionated (all dermal), $\alpha 8$ integrin-high or integrin-low populations seeded on ECM protein-coated dishes (10 μ g/ml of each protein) for 12 hr. N, nephronectin; L, laminin; N+L, nephronectin and laminin. Data are means \pm SEM from three independent wells.

family member EGFL6/MAEG. Like nephronectin, EGFL6 is an $\alpha 8\beta 1$ ligand that is expressed in mouse skin (Osada et al., 2005). In wild-type and *Npnt*^{+/-} skin, EGFL6 was expressed in dermal condensates at E14.5 and in the dermal sheath at E16.5–E18.5 (Figures S3G and S3H). In newborn skin (P1 and P5), EGFL6, like nephronectin, localized to the K15-positive bulge (Figure S3G and Figure 1). However, in adult skin, EGFL6 was only deposited in the basement membrane of the upper bulge, which is CD34 positive and K15 negative (Figure S3G). *Egfl6* mRNA was highly upregulated in CD34+ $\alpha 6$ ^{high} cells relative to other basal keratinocytes (Figure S3I), indicating that EGFL6 in the upper bulge is of epidermal origin.

In control skin, the arrector pili muscles inserted below the EGFL6-positive zone of the hair follicles (Figures 4N and 4P). However, in *Npnt*^{-/-} skin, EGFL6 deposition in the upper bulge was increased, and the muscles inserted into the EGFL6-positive zone (Figures 4O and 4P; see also Figures S3G

and 3J–3L). Although the site of insertion of the APM was altered in *Npnt*^{-/-} skin, piloerection could still be induced by treatment with the $\alpha 1$ -adrenergic receptor agonist phenylephrine, which induces smooth muscle contraction (Figures S3M and S3N). Our data reveal that nephronectin anchors the APM to the bulge and that, in the absence of nephronectin, the site of insertion shifts upward to the EGFL6-positive zone (Figure 4Q).

the major effect of *Npnt* deletion was to change the site of muscle attachment to the follicle. In control mice, the APM attached to the K15-positive bulge, whereas in *Npnt* knockout mice, the attachment was higher up the follicle (Figures 4G, 4H, and 4K–4M). In *Npnt*^{+/-} skin, 88.3% of muscle attachments located on the bulge. However, in the knockout, only 23.2% were on the bulge, and 76.3% were located above the bulge. These results show that nephronectin is required to anchor the APM to the bulge.

The observation that loss of nephronectin led to a specific upward shift in APM insertion point, rather than randomizing the insertion sites, led us to investigate whether there was compensatory change in the distribution of the nephronectin

and 3J–3L). Although the site of insertion of the APM was altered in *Npnt*^{-/-} skin, piloerection could still be induced by treatment with the $\alpha 1$ -adrenergic receptor agonist phenylephrine, which induces smooth muscle contraction (Figures S3M and S3N).

Our data reveal that nephronectin anchors the APM to the bulge and that, in the absence of nephronectin, the site of insertion shifts upward to the EGFL6-positive zone (Figure 4Q).

$\alpha 8$ Integrin Determines Specificity of Arrector Pili Muscle Attachment Site to the Bulge

Because the $\alpha 8\beta 1$ integrin mediates nephronectin binding, we examined whether APM anchorage to the bulge was also disrupted in $\alpha 8$ integrin (*Itga8*) knockout mice (Müller et al.,

1997). H&E-stained sections of adult dorsal telogen *Itga8*^{-/-} skin, like *Npnt*^{-/-} skin, did not show any gross abnormalities (Figures 5A and 5B). Nephronectin deposition in the bulge was normal, but nephronectin was lacking in the APM, demonstrating that the $\alpha 8$ integrin is essential for deposition of nephronectin in the APM, but not in the bulge (Figures 5K and 5L). αv integrins, which, like $\alpha 8$, mediate nephronectin adhesion (Brandenberger et al., 2001), showed normal expression in the dermal papilla and APM of *Itga8*^{-/-} skin (Figures S4A–S4D).

Arrector pili muscles were still associated with hair follicles in *Itga8*^{-/-} skin, with a small reduction in the number of APM (Figures 5C and 5D and Figure S4E), but, as in the case of *Npnt*^{-/-} skin, their selectivity for the bulge was disrupted. The proportion of muscles that attached to the K15-positive, nephronectin-positive, bulge region was decreased (Figures 5E–5G), and the proportion that inserted above the bulge, in the EGFL6-positive region, was increased (Figures 5H–5J). The striking difference between *Npnt*^{-/-} and *Itga8*^{-/-} skin was that, whereas in the absence of nephronectin, $\alpha 8\beta 1$ -positive APM cells showed selectivity for the EGFL6-positive region, APM lacking $\alpha 8\beta 1$ lost their selectivity for nephronectin-positive basement membrane and inserted into both nephronectin- and EGFL6-positive regions (Figure 4Q and Figure 5M).

We conclude that the site of APM attachment to the hair follicle is determined by the combination of $\alpha 8\beta 1$ expression on smooth muscle cells and nephronectin deposition by bulge stem cells.

Epidermal Wnt/ β -Catenin Signaling Determines Regional Nephronectin and $\alpha 8$ Integrin Expression

Because bulge-specific expression of nephronectin creates the niche for APM cell anchorage and differentiation, we next investigated the molecular mechanism of regional nephronectin expression. The two sites of epidermal nephronectin deposition, the bulge and hair germ, are sites of active Wnt/ β -catenin signaling (Lowry et al., 2005; Nguyen et al., 2009), leading us to investigate whether nephronectin is a Wnt target gene. We activated Wnt/ β -catenin signaling by topical application of 4-hydroxytamoxifen (4-OHT) to the back skin of adult telogen K14 Δ N β -cateninER mice, which express stabilized β -catenin fused with the C terminus of a mutant estrogen receptor under the control of the K14 promoter (Lo Celso et al., 2004). This resulted in a 4-OHT dose-dependent increase in epidermal mRNA encoding nephronectin (Figure 6A) and the bulge Wnt effectors Tcf3 and Tcf4 (Figure S5A). In contrast, *Egfl6* mRNA levels did not change (Figure 6A). Upregulation of nephronectin protein was observed in the bulge and the ectopic hair follicles of 4-OHT-treated K14 Δ N β -cateninER mice (Figures 6B and 6C; see also Lo Celso et al., 2004), whereas deposition of EGFL6 was unaffected (Figures 6D and 6E).

Using UCSC Genome Browser, several conserved putative binding sites for Lef/Tcfs in the *Npnt* locus were identified. We therefore performed chromatin immunoprecipitation (ChIP) assays with an antibody to Tcf4, which, together with Tcf3, is specifically expressed in the bulge (Nguyen et al., 2009), and chromatin from cultured 4-OHT-treated K14 Δ N β -cateninER keratinocytes. One of the conserved sites (site 4) showed consistent enrichment for Tcf4 relative to the control FLAG antibody (Figure 6F), demonstrating that nephronectin is a direct target of Tcf4.

We then analyzed the expression of nephronectin in K14 Δ NLef1 mice that express N-terminally deleted Lef1, which lacks the β -catenin-binding site, under the control of the K14 promoter (Niemann et al., 2002). Δ NLef1 acts as a dominant-negative inhibitor of Wnt/ β -catenin signaling by blocking formation of β -catenin/Lef/Tcf complexes. We separated adult bulge and other basal keratinocytes from K14 Δ NLef1 transgenic mice by FACS and examined the expression levels of nephronectin by Q-PCR. In bulge keratinocytes, nephronectin expression was decreased, whereas in nonbulge keratinocytes, expression was upregulated (Figure 6G). Consistent with this, in K14 Δ NLef1 skin, nephronectin deposition in the bulge and hair germ was decreased, whereas nephronectin deposition in the interfollicular epidermis was increased (Figures 6H and 6I).

We also examined the effects of BMP and Notch signaling on nephronectin expression (Figures S5B and S5C). Inhibition of BMP signaling by expression of the BMP antagonist Noggin under the control of the K14 promoter (Sharov et al., 2009) increased nephronectin expression in the bulge. However, activation of Notch signaling by expression of the Notch intracellular domain via the K14 promoter (Estrach et al., 2006) did not affect nephronectin expression. The upregulation of nephronectin in K14Noggin skin fits well with the upregulation of Wnt signaling that occurs on BMP inhibition in this model (Sharov et al., 2009). These results indicate that activation of Wnt/ β -catenin signaling in the bulge and hair germ induces nephronectin expression, whereas Wnt/ β -catenin signaling in the interfollicular epidermis normally suppresses nephronectin.

To determine whether epidermal β -catenin activation was sufficient to induce $\alpha 8\beta 1$ expression in adjacent dermal cells, we examined 4-OHT-treated mice expressing the Δ N β -cateninER transgene. When Wnt/ β -catenin signaling was activated in K14 Δ N β -cateninER transgenic mice, $\alpha 8$ integrin was ectopically expressed by dermal cells adjacent to ectopic hair follicles, colocalizing with nephronectin (Figures 6J–6L). When β -catenin was selectively activated in bulge stem cells by 4-OHT treatment of K15 Δ N β -cateninER mice (Baker et al., 2010), nephronectin was upregulated in the bulge and there was a corresponding increase in bulge-associated $\alpha 8$ integrin-expressing dermal cells (Figures 6M and 6N). These observations establish that epidermal Wnt/ β -catenin signaling induces expression of $\alpha 8$ integrin in adjacent dermal cells.

Taken together, our data show that nephronectin is a Wnt/ β -catenin target gene and that Wnt/ β -catenin signaling in epidermis determines not only region-specific nephronectin deposition, but also, as a result, the location of $\alpha 8$ integrin-expressing mesenchymal cells.

DISCUSSION

It has previously been suggested that heterogeneity in basement membrane composition may help to establish distinct stem cell niches; however, direct evidence has been lacking (Akiyama et al., 1995; Fuchs, 2008; Hall and Watt, 1989; Scadden, 2006; Spradling et al., 2001; Watt and Hogan, 2000). Our study identifies how local variation in epidermal basement membrane composition is established and demonstrates that the specific composition of the bulge ECM not only provides a specialized

(E) Percentage of hair follicles with arrector pili muscles, determined from histological sections.

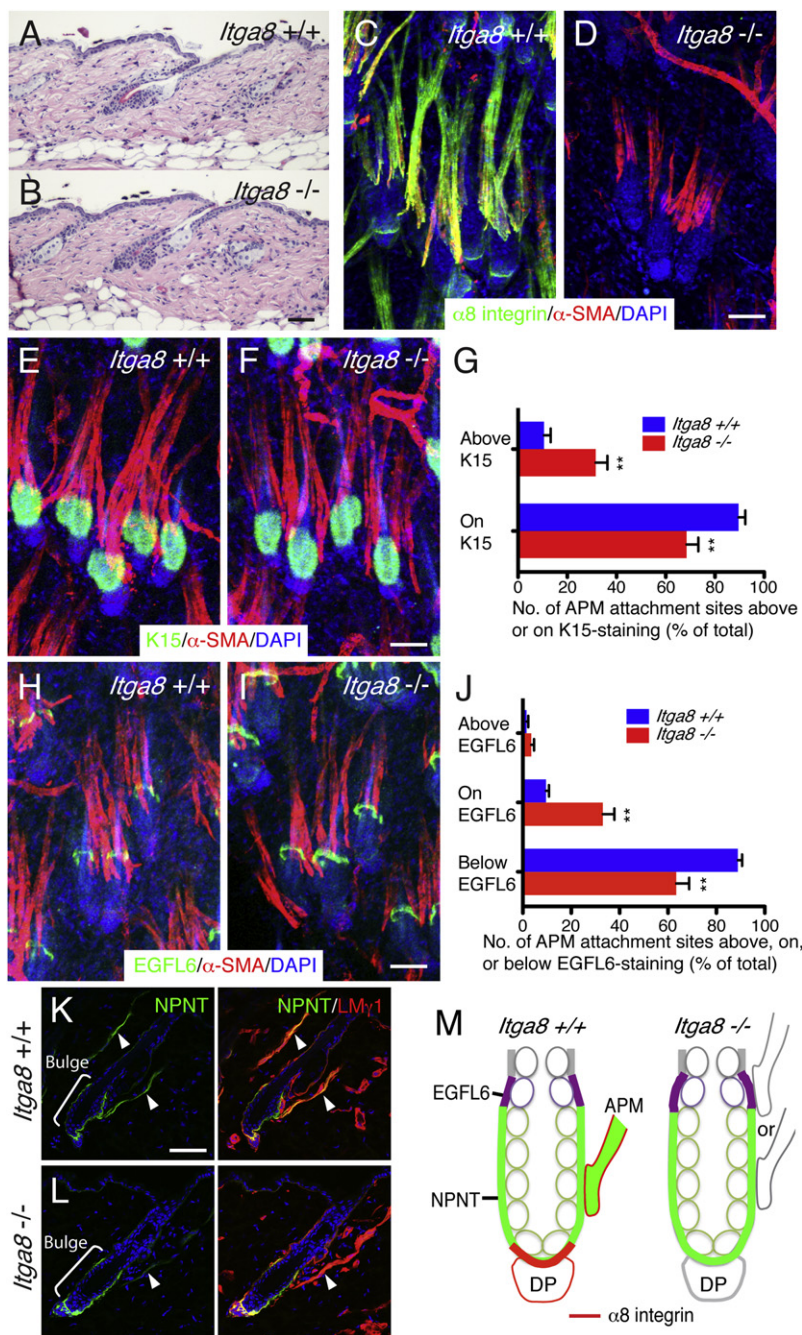

(F) Maximum projection image of dorsal wild-type skin whole-mount stained for α -SMA (green), SM22 α (red), and nuclei (blue). White brackets indicate groups of hair follicles that share arrector pili muscles.

(G–J) Whole mounts (G and H) were immunostained for K14 (green) and α -SMA (red), with DAPI counterstain (blue). Arrow (H) indicates hair follicle without associated APM. Brackets indicate bulge. Percentage of follicles with arrector pili muscles (I) and number of APM attachments per hair follicle (J).

(K–M) Whole mounts were immunostained for K15 (green) and α -SMA (red), with DAPI counterstain (blue). Position of APM attachment sites relative to K15-positive bulge was quantified (M).

(N–P) Whole mounts were immunostained for EGFL6 (green) and α -SMA (red), with DAPI counterstain (blue). Position of APM attachment sites relative to EGFL6-positive zone was quantified (P).

(Q) Schematic summary of data. (Green) Nephronectin. (Purple) EGFL6. (Red) α 8 integrin. (Green circles) K15-positive bulge cells. In the presence of nephronectin, arrector pili muscles insert at the bulge. In the absence of nephronectin, EGFL6 expression in the upper bulge is increased, and muscles insert in that region. α 8 integrin colocalizes with nephronectin in the basement membrane of the hair germ adjacent to the dermal papilla (DP). In the absence of

environment for bulge stem cells, but also for adjacent mesenchymal cells (Figure 7).

Sox9-positive bulge stem cells are specified in early hair follicle morphogenesis, just after birth (Nowak et al., 2008). This coincides with restriction of nephronectin deposition to the bulge basement membrane and an associated accumulation

progenitors through adhesion to nephronectin deposited in the early bulge. The synergistic effect of nephronectin and laminin, another component of the bulge basement membrane (Figure S1B), in inducing smooth muscle markers is consistent with the positive role of laminin in intestinal smooth muscle differentiation (Bolcato-Bellemin et al., 2003).

nephronectin, EGFL6 is expressed in that region, but there is no colocalization with $\alpha 8$ integrin. All skin samples were from the back of 7-week-old telogen mice.

In (E), (I), (J), (M), and (P), data are means \pm SEM from three mice; 100 follicles per mouse. Scale bars, 50 μ m, except for (F) (100 μ m). See also Figure S3.

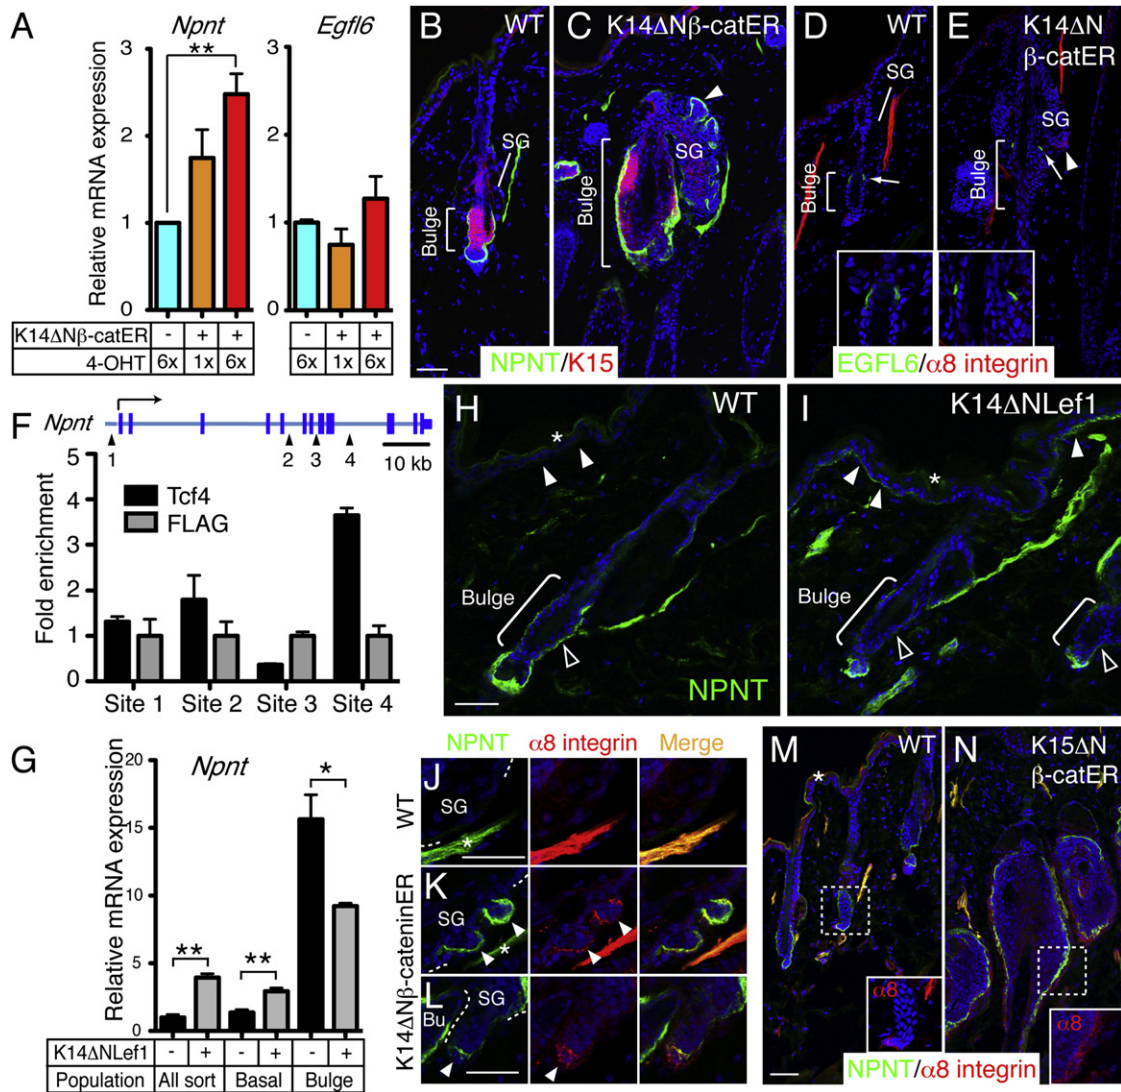

Figure 6. Regulation of Regional Nephronectin- $\alpha 8$ Integrin Interaction by Wnt/ β -Catenin Signaling

(A) Q-PCR of *Npnt* and *Egfl6* mRNA in keratinocytes isolated from skin of wild-type ($\Delta\beta$ -catER⁻) and K14 $\Delta\beta$ -cateninER mice ($\Delta\beta$ -catER⁺) that had been treated with 4-OHT for the number of times indicated. Data are means \pm SEM from three mice.

(B–E) Dorsal skin of wild-type and K14 $\Delta\beta$ -cateninER mice treated 6x with 4-OHT and immunostained for nephronectin (green; B and C) or EGFL6 (green; D and E) and K15 (red; B and C) or $\alpha 8$ integrin (red; D and E), with DAPI counterstain (blue). Arrowheads indicate ectopic hair follicle arising from sebaceous gland (SG). Arrows indicate EGFL6 staining. Inserts show higher-magnification views of EGFL6 staining around the bulge.

(F) ChIP using antibodies against Tcf4 and FLAG in K14 $\Delta\beta$ -cateninER keratinocytes. Primers surrounding four conserved putative binding sites for Lef/Tcfs at the *Npnt* locus were used to detect the precipitated DNA fragments. Data are means \pm SEM of two independent experiments.

(G) Q-PCR of mRNA from FACS-isolated bulge, nonbulge (basal), and total basal (all sort) keratinocytes from wild-type and K14 $\Delta\beta$ -cateninER adult telogen skin. Data are means \pm SEM from three mice.

(H and I) Wild-type and K14 $\Delta\beta$ -cateninER skin immunostained for nephronectin (green), with DAPI counterstain (blue). Basement membrane of interfollicular epidermis (white arrowheads) and bulge (open arrowheads) is indicated.

(J–N) Sections of wild-type (J and M), K14 $\Delta\beta$ -cateninER (K and L), and K15 $\Delta\beta$ -cateninER (N) skin treated 6x (J–L) or 9x (M and N) with 4-OHT and immunostained for nephronectin (green) and $\alpha 8$ integrin (red), with DAPI counterstain (blue). Arrowheads indicate ectopic hair follicles. Asterisks in (J) and (K) indicate arrector pili muscles. Inserts in (M) and (N) show magnified images of $\alpha 8$ integrin staining around the bulge.

Asterisks in (H), (I), and (M) indicate nonspecific staining. Scale bars, 50 μ m. See also Figure S5.

Deletion of nephronectin resulted in upregulation of the nephronectin-related protein EGFL6 and a corresponding change in the arrector pili muscle insertion site from the bulge to the EGFL6-positive zone above. The LFEIFEIER motif that mediates the high-

affinity interaction of nephronectin with $\alpha 8\beta 1$ integrin is lacking in EGFL6 (Osada et al., 2005; Sato et al., 2009), and this is the likely explanation for the specific association of $\alpha 8$ -positive cells with nephronectin in wild-type skin. On deletion of the $\alpha 8$ integrin,

Figure 7. Model Depicting Role for Nephronectin- α 8 β 1 Interactions in Creating the Niche for the Arrector Pili Muscle at the Hair Follicle Bulge

During hair morphogenesis in neonatal skin, early bulge stem cells locally deposit nephronectin in the bulge basement membrane. Nephronectin induces neighboring mesenchymal progenitors to differentiate into α 8 integrin-positive APM cells, which adhere specifically to nephronectin, establishing a stable anchorage to the bulge that is maintained throughout adult life. In the absence of nephronectin, the APM is not anchored to the bulge but attaches above the bulge, where there is compensatory upregulation of EGFL6. Lack of nephronectin also disturbs α 8 integrin-mediated hair follicle-dermal papilla interactions (Figure S3). In the absence of α 8 integrin, nephronectin is still deposited in the bulge, but the selectivity of the APM interaction is lost, and muscles are anchored both to the nephronectin-positive bulge and the EGFL6-positive upper bulge.

nephronectin was still expressed in the bulge, but the specificity of APM association with nephronectin was lost, and muscles inserted into both the nephronectin-positive and EGFL6-positive zones. This is probably because, in the absence of α 8 β 1, adhesion to nephronectin is mediated via the α v integrins, which is a lower-affinity interaction (Brandenberger et al., 2001) (Figure S4).

Though the APM is known to attach to the bulge via a tendon, the tendon cells have not been identified (Barcaui et al., 2002; Guerra Rodrigo et al., 1975). We showed that the tendon/ligament extracellular matrix protein periostin (Horiuchi et al., 1999; Norris et al., 2007) was strongly expressed in bulge stem cells and deposited locally around the bulge. Furthermore, the gene signature of bulge stem cells includes many tendon-related genes, such as *Scx* (scleraxis), *Mitf*, *Igfbp5*, *Fbln1* (fibulin-1), *Postn* (periostin), *Tnc* (tenascin-C), *Sparc*, *Igfbp6*, and *Fgf18* (Brent et al., 2003; Jelinsky et al., 2010; Morris et al., 2004; Tumber et al., 2004). We therefore propose that bulge stem cells function as tendon cells in providing a physical connection for the APM. The immobility of the bulge ensures that APM attachment is stable regardless of the stage of the hair growth cycle.

We did not obtain any evidence that, as has been suggested, the APM determines the location of bulge stem cells (Akiyama et al., 1995; Christiano, 2004). The delocalization of the muscle that occurred on loss of nephronectin had no clear effect on the bulge, as judged by bulge morphology and expression of keratin 15 and CD34. Thus, nephronectin expression by bulge stem cells provides a niche for APM cells but is not an essential component of the epidermal stem cell niche.

Wnt/ β -catenin signaling is well known to play a role in controlling epidermal stem cell renewal and lineage selection and in reciprocal interactions with the dermal papilla (Alonso and Fuchs, 2003; Watt and Collins, 2008). However, a role for Wnt/ β -catenin signaling in regulating the APM was previously unknown. We demonstrate that nephronectin, unlike EGFL6, is a direct target of Wnt/ β -catenin signaling. Nephronectin expression is upregulated by Wnt/ β -catenin activation, directly or via inhibition of BMP signaling, in the epidermis, and as a result, there is a corresponding upregulation of α 8 integrin expression in the adjacent dermis.

The consequences of activating Wnt/ β -catenin signaling were context dependent. Activation in the bulge upregulated nephronectin, whereas activation in the interfollicular epidermis did not. Conversely, expression of Δ NLef1, which inhibits Wnt signaling, stimulated nephronectin expression in the interfollicular epidermis and downregulated expression in the bulge. A likely explanation for the region-specific effects of Δ NLef1 is that Δ NLef1 expression in the bulge inhibits β -catenin-dependent induction of nephronectin expression by Tcf3 or Tcf4, whereas in the interfollicular epidermis, Tcf/Lef transcription factors are not expressed, so Δ NLef1 regulates nephronectin expression independently of the Wnt pathway (Nguyen et al., 2006).

The APM plays an important role in thermoregulation because it is responsible for piloerection, which traps warm air at the skin surface. Piloerection is also believed to cause constriction of the sebaceous glands, aiding release of sebum onto the skin surface (Poblet et al., 2004). Furthermore, as Charles Darwin noted in 1872, involuntary erection of hairs, feathers, and other dermal appendages is an evolutionarily conserved response to emotional disturbance (Darwin, 1872). Our results provide new insights into the mechanism of arrector pili muscle morphogenesis and answer the long-standing question of why the arrector pili muscle is attached to the hair follicle bulge (Akiyama et al., 1995).

EXPERIMENTAL PROCEDURES

Generation and Experimental Treatment of Mice

Npnt knockout mice, *Itga8* knockout mice, and K14 Δ NLef1, K14 Δ N β -catenin^{ER} (D2 line), and K15 Δ N β -catenin^{ER} transgenic mice have been described previously (Baker et al., 2010; Linton et al., 2007; Lo Celso et al., 2004; Müller et al., 1997; Niemann et al., 2002). The Δ N β -catenin^{ER} transgene was activated by topical application of 4-hydroxytamoxifen (4-OHT; Sigma) dissolved in acetone. Shaved back skin was treated topically with 1.5 mg of 4-OHT in 200 μ l of acetone three times per week for 2 weeks unless otherwise specified.

Gene Expression Analysis

For microarray analysis, CEL format files of the gene expression profiles of K15-positive mouse bulge stem cells (GSE1096) were obtained from the NCBI's GEO (Gene Expression Omnibus) website (Morris et al., 2004) and were analyzed with Genespring X10.0 (Agilent Technologies).

Immunohistochemistry and Whole-Mount Preparations

Immunofluorescence staining of tissue sections was performed by conventional methods. Whole-mount immunostaining of mouse dorsal skin was performed by applying the methods established for whole-mount immunostaining of mouse tail epidermis, with some modifications (Braun et al., 2003). Embryonic and adult dorsal skin was dissected, and the subcutaneous fat tissue was removed. Skin was fixed with 4% paraformaldehyde/PBS for 1 hr at room temperature and blocked with a blocking buffer for 1 hr. Skin samples were incubated with primary antibodies diluted in blocking buffer overnight at room temperature, washed with 0.2% Tween 20/PBS for 4 hr, and then incubated with DAPI and secondary antibodies diluted in blocking buffer overnight at room temperature. Finally, skin samples were washed with 0.2% Tween 20/PBS for 4 hr at room temperature and mounted.

Images were acquired using a Leica TCS SP5 Tandem Scanner confocal microscope. Z stack maximum projection images of whole-mount preparations were produced using LAS AF software (Leica).

Quantitative RT-PCR

Total RNA was isolated using an RNeasy Mini kit (QIAGEN) with on-column DNase I digestion. cDNA was synthesized using SuperScript III (Invitrogen). RT-PCR was performed using SYBR green super mix (ABI). The expression levels of target genes were normalized by *Gapdh* levels utilizing a standard curve method. Primers used in this study are listed in Supplemental Information.

FACS

Mouse adult dorsal telogen keratinocytes were isolated, stained for $\alpha 6$ integrin and CD34, and sorted as described previously (Silva-Vargas et al., 2005). For dermal cell sorting, P1 newborn dorsal skin was treated with 5 mM EDTA/PBS at 37°C for 3 hr. The epidermal sheet, including hair follicles, was peeled off and discarded. The dermis was incubated in FAD medium containing 0.2% collagenase (GIBCO) and 2U/ml of DNase I (Sigma) at 37°C for 1 hr. The dermal cell suspension was stained for $\alpha 8$ integrin. Cells were sorted with a FACSAria according to $\alpha 8$ integrin expression after gating out dead cells and cells with high forward and side scatter.

Statistics

P values were determined using the Student's t test: * $P < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

Additional Experimental Procedures

These are described in the Supplemental Information.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Extended Experimental Procedures, five figures, and five tables and can be found with this article online at doi:10.1016/j.cell.2011.01.014.

ACKNOWLEDGMENTS

We thank Vladimir Botchkarev for K14-Noggin skin and Takako Sasaki for Fibulin-1 antibody. We gratefully acknowledge the technical assistance of the core resources of the CRUK Cambridge Research Institute. We thank the entire Watt lab for valuable reagents, suggestions, and advice. This work was funded by Cancer Research UK and supported by the University of Cambridge and Hutchison Whampoa Ltd. We also gratefully acknowledge financial support from the NIH (NS19090 to L.F.R.), from the Uehara Memorial Foundation (H.F.), and from EU FP7 (Optistem).
