#### ABSTRACT

Worsening of verbal fluency after treatment with deep brain stimulation in Parkinson's disease patients is the 18 most often reported cognitive adverse effect. The underlying mechanisms of this decline are not well understood. 19 The present focused review assesses the evidence for the reliability of the often-reported decline of verbal 20 fluency, as well as the evidence for the suggested mechanisms including disease progression, reduced medication 21 levels, electrode positions, and stimulation effect vs. surgical effects. Finally, we highlight the need for more sys- 22 tematic investigations of the large degree of heterogeneity in the prevalence of verbal fluency worsening after 23 DBS, as well as provide suggestions for future research. 24

#### 1. Introduction

This focused review was invited as a result of the II. International 37Conference on Deep Brain Stimulation (Düsseldorf, March 2016), and 38it aims to provide an up-to-date status on the incidence and potential 39 explanations for the often-reported verbal fluency (VF) decline after 40deep brain stimulation (DBS) in Parkinson's disease (PD), as well as a 41 set of pointers for future research. Several explanations have been pro-42 posed including disease progression, reduced medication levels, 43 microlesions, as well as electrode location and stimulation itself, but 44 with no clear conclusions drawn so far. Advancing our understanding 45 46 of this aspect of DBS contributes to the continued improvement of the DBS treatment, as well as to our understanding of the effect mechanisms 47 behind DBS. 48

The timeliness of this focused review has allowed us to include three 49 50recently published meta-analyses on neuropsychological adverse effects (including VF worsening) after DBS in PD [12,80,81]. As revealed 51by Combs et al. [12], there are relatively few studies assessing VF de-5253clines after DBS in the internal globus pallidus (GPi) compared to DBS in subthalamic nucleus (STN), which is also mirrored in this review. 54This underrepresentation of GPi studies is reflective of a general tenden-5556cy in the field to prefer STN to GPi as target for DBS in PD [63], as well as 57of potential differences in cognitive adverse effects between the two 58targets [12].

E-mail address: linahn@clin.au.dk (A. Højlund).

The structure of this review centers around two overarching 59 questions: 60

- 1. What is the evidence for verbal fluency (VF) worsening after DBS- 61 treatment in PD? 62
- 2. What are the possible mechanisms underlying such a decline?

In response to 1, we will review the evidence for the commonly re- 64 ported VF decline in relation to pre- and post-surgery evaluations for 65 both STN- and GPi-DBS, as well as highlight the large degree of hetero- 66 geneity in the incidence of VF worsening following DBS, which has not 67 been investigated systematically yet. 68

In response to 2, we will review the literature in relation to sug- 69 gested explanations such as disease progression, reduced medication 70 levels, electrode positions, and stimulation vs. lesion effects. 71

### 2. Background

PD is a progressive neurodegenerative disease characterized by the 73 motor symptoms rest tremor, postural instability, rigidity and bradyki-74 nesia (slowness of movement) and a variety of non-motor symptoms 75 including cognitive decline and worsening of VF [53,86]. 76

DBS in STN and GPi has been shown to effectively alleviate PD pa-77 tients' motor symptoms when medication is no longer a viable treat-78 ment [17,21,32,36,46,87,88]. However, the effects of DBS on cognition 79 are still not well understood [79]. And as already mentioned, one of 80 the most consistently reported detrimental effects of DBS in PD is a 81 worsening of VF [12,48,69,79-81]. VF deficits are also part of the PD 82 symptomatology prior to DBS surgery [24], but the underlying cause 83 of the worsening after DBS is still an open question. 84

# **ARTICLE IN PRESS**

85 Verbal fluency is tested with a task requesting the patient, within a 86 minute, to name as many words as possible starting with a specific letter (e.g., F, A, or S; known as phonemic or letter fluency) or stemming from 87 88 a given category (e.g., animals; known as semantic or category fluency) [8,35]. Deficits in verbal fluency may thus come about from both linguis-89 tic and executive dysfunctions as it involves a multitude of cognitive 90 processes including lexical search, memory retrieval, executive func-9192 tioning, response monitoring, inhibition and selection [35,59].

### 93 3. Evidence for Worsening of Verbal Fluency After DBS

When assessing the evidence for VF worsening after DBS, it is impor-94tant to note the point raised by Woods et al. [78] that far from all studies 9596 reporting on cognitive sequelae of DBS include the sufficient sample sizes to detect even large effect sizes. In fact, in their sample of 30 pub-97 lished studies, only two studies did. This urges caution in interpreting 98 the results of most individual studies on this topic and places a strong 99 emphasis on the results of carefully conducted meta-analyses, and in 100 the absence of such on the results from well-powered randomized con-101 trol trial (RCT) studies. 102

Fortunately, in relation to the evidence for VF worsening after DBS, two meta-analyses have aptly summed up the available literature on pre- and post-surgery evaluations of the cognitive sequelae of DBS at least three months after surgery.

Parsons et al. [48] conducted a meta-analysis on 28 studies from 107 1990 to 2006 on STN-DBS meeting inclusion criteria which included 108 reporting of change scores, and neuropsychological evaluations at 109110 baseline and follow-up. Among the 28 studies, 16 reported data for phonemic VF (355 patients), and 16 reported data for semantic VF (337 pa-111 tients), summing up to 21 studies in total reporting on phonemic and/or 112 semantic VF. On the basis of this, they found average effect sizes of mod-113 114 erate size (0.51 and 0.73) for both phonemic and semantic VF declines. 115Combs et al. [12] extended Parsons et al.'s [48] meta-analysis from 2006 by analyzing studies with baseline and follow-up neuropsycholog-116 ical evaluations from both STN- and/or GPi-DBS treatments in PD. These 117 meta-analyses revealed that both targets resulted in moderate effect 118 size declines in both phonemic and semantic VF. However, the available 119 evidence for the effects of GPi-DBS on VF are still relatively sparse, and 120 therefore the observed slight disadvantage for STN is inconclusive. In 121 their two meta-analyses on STN-DBS and GPi-DBS, there are a few in-122 consistencies. First, there are overlapping study cohorts (Ardouin et al. 123 124 [5] and Pillon et al. [50]; Daniels et al. [15] and Witt et al. [74]). Second, the reported total number of studies included vs. those listed in the 125overview table do not exactly match ([12], Table 1). And third, the 126 127total numbers of patients reported for the phonemic VF task for both STN-DBS and GPi-DBS exceed the total sums of included study patients 128129in the overview table ([12], Tables 1–3). However, these inconsistencies are minor, and we deem the reported results credible. 130

There is thus reliable evidence for a worsening of moderate effect size in both phonemic and semantic VF after STN-DBS. The evidence for a similar decline in GPi-DBS is still too sparse to be considered reliable, but there are subtle tendencies suggesting a slight disadvantage for STN (when considering other cognitive adverse effects, as well).

Following the publication of the results from the large RCT study on STN- and GPi-DBS by the CSP-468 Study Group ([21,55,70,71], the debate on which target – STN or GPi – to select for DBS in PD has received renewed attention [42,73].

### 140 **4. Suggested Causes of Worsening of Verbal Fluency**

#### 141 4.1. Disease Progression

In order to assess the continued disease progression as a potential
explanation of the reported VF declines, studies are needed which include a matched PD control group on best medical treatment (BMT)
with VF testing at similar baseline and follow-up intervals as the DBS

group. Very recently, two meta-analyses were conducted on such studies comparing VF declines in STN-DBS PD patients and in PD patients on 147 BMT [80,81]. Both meta-analyses seem to confirm that PD patients after 148 STN-DBS treatment experience VF worsening to a larger extent 149 (i.e., moderate to small effect sizes) than matched PD patients on BMT. 150 However, these results should be interpreted with considerable caution 151 due to substantial methodological issues in both meta-analyses. 152

First, Wyman-Chick [80] included eligible studies published be- 153 tween 2000 and June 2014, but only 9 out of 140 identified studies 154 met the study's inclusion criteria for phonemic VF and also only 9 for se-155 mantic VF (i.e., in total, 10 studies were included: 8 with both phonemic 156 and semantic, 1 with only phonemic, and 1 with only semantic VF data). 157 Furthermore, the author relied on comparisons of the two groups' VF 158 scores only at the follow-up evaluation (and not the groups' change 159 scores). But a difference in follow-up scores is not necessarily reflective 160 of a difference in change scores. Both Marshall et al. [38] and Zangaglia 161 et al. [85] are examples of this discrepancy. In Marshall et al. [38] neither 162 phonemic nor semantic VF changes were significantly different be- 163 tween the DBS-treated and BMT groups (p = 0.41 and p = 0.60, respec- 164 tively). However, when only the follow-up values were included in 165 Wyman-Chick's [80] meta-analysis, the differences between the two 166 groups were assigned adjusted effects sizes of -0.33 and -0.21 for 167 phonemic and semantic VF, respectively, denoting small, but substan- 168 tial, differences between the two groups at follow-up, Zangaglia et al. 169 [85] reported a significant difference in phonemic VF scores between 170 the two groups at the 36-month-follow-up. However, there was already 171 a noticeable difference between the two groups at the baseline, albeit 172 non-significant, and the STN-DBS PD group's phonemic VF scores did 173 not change significantly between baseline and follow-up (p = 0.164). 174 Hence, none of the included differences in follow-up VF scores from 175 the two studies adequately reflect a reduction in VF scores due to the 176 DBS treatment compared to BMT. 177

Second, Xie et al. [81] included studies published until June 2015 and 178 focused on potential differences in the two groups' change scores. For 179 the VF deficits, this meant that only 6 and 4 out of 172 identified articles 180 were included for phonemic and semantic VF, respectively (these num- 181 bers are available in the article's supplementary material). Unfortunate- 182 ly, the authors included both Witt et al. [75] and Daniels et al. [15] as 183 separate studies, yet these are overlapping cohorts (Witt et al. [75] ana- 184 lyzed a subset of the patients in Daniels et al. [15]). Furthermore, it 185 seems the authors selected the wrong standard deviation (SD) values 186 from the study by Castelli et al. [9] and Rothlind et al. [55]. They wrong-187 fully interpreted the SD values of the mean values at the follow-up eval- 188 uations as belonging directly to the change scores. Castelli et al. [9] is 189 also included in Wyman-Chick's [80] meta-analysis where she has 190 interpreted exactly the same SD values as belonging to the mean values 191 at the follow-up evaluation. Furthermore, it is not clear why only the 192 phonemic (and not also semantic) VF values were included from Cilia 193 et al. [11], Merola et al. [40], and Rothlind et al. [55] under "Processing 194 speed" in Table 3), and vice-versa for the semantic (but not phonemic) 195 VF values from Williams et al. [72], when both sets of VF values were 196 readily available in all four studies. Including these values could have in- 197 creased the number of properly included studies for both VF scores to 198 six (when also accounting for the overlap between Witt et al. [75] and 199 Daniels et al. [15]). 200

Hence, both meta-analyses suffer from relatively low power ([81], in 201 particular), as well as from substantial methodological issues. We therefore consider their combined evidence relatively inconclusive. 203

However, if we focus on the two RCT studies included in the meta-204 analyses, i.e., Witt et al. [74] and Rothlind et al. [55], they both provide 205 evidence in the form of well-powered direct comparisons of the change 206 scores of both DBS and BMT groups. Both report significant worsening of 207 both phonemic and semantic VF in the DBS groups compared to the 208 BMT group between baseline and after 6 months. In fact, Rothlind 209 et al. [55] included both an STN- and a GPi-DBS group, and both groups 210 showed very similar declines in VF after DBS compared to the BMT 211

## <u>ARTICLE IN PRESS</u>

group. Hence, disease progression does not seem to be able to account

 $_{213}$   $\,$  for the observed worsening of VF after DBS, regardless of target.

#### 214 4.2. Reduced Dopaminergic Medication Levels

215STN-DBS (but not GPi-DBS) is often followed by a significant reduction in dopaminergic medication [21]. Based on this general observation 216as well as a correlation between greater reduction in dopaminergic 217levels and greater worsening of phonemic VF in their own study, 218219 Sáez-Cea et al. [56] suggested that reduced medication levels may play a role in the observed VF declines. However, to the best of our knowl-220221 edge, only one study [22] has reported that PD patients OFF dopaminergic medication performed worse on (semantic) VF than healthy controls 222 whereas there was no significant difference when the patients were ON 223 medication. This could suggest a beneficial role of dopaminergic medi-224 cation on VF performance (as briefly mentioned by Cools [13] with ref-03 erence to Gotham et al. [22]), and by extension a detrimental role of 226reduced medication levels in the observed VF decline after STN-DBS. 227But Gotham et al. [22] also reported no significant differences within 228the PD group on (semantic) VF performance for ON and OFF dopaminer-229gic medication, which, in essence, is the crucial and most sensitive con-230trast in this respect, and thus not suggestive of an effect of dopaminergic 231 medication on VF performance. 232

Nonetheless, since changes in dopaminergic medication levels be-233234tween baseline and follow-up are often compared to the observed declines in VF after DBS, this allowed the aforementioned meta-analyses 235by Parsons et al. [48] and Combs et al. [12] to also test for such a relation. 236Neither of them found any relation between reductions in medication 237levels and VF decline following DBS. And even though this is in essence 238239 a null result, the combined evidence of the two meta-analyses strongly 240suggests that reduced levels of dopaminergic medication (after STN-241 DBS) cannot account for the observed VF declines after DBS.

### 242 4.3. Electrode Positions

243 A few studies have investigated the effects of electrode locations on 244 the observed worsening of VF after DBS. And even though the evidence is still sparse, this factor seems to affect the VF performance after DBS to 245a larger degree than disease progression and reduced medication levels. 246 Witt et al. [75] observed a significant worsening of semantic VF in a 247 group of STN-DBS PD patients compared to a PD control group on BMT. 248 By dividing the STN-DBS group into decliners and stable performers, 249they found that the active contacts of 75% (9 out of 12) of the decliners 250lay outside the pseudo-volume created on the basis of the active con-251tacts of the 19 stable performers. Especially in the left hemisphere, 252253most of the decliners' active contacts were also placed more ventrally.

Okun et al. [46], on the other hand, altered the active contact for 254stimulation in both unilateral STN-DBS and GPi-DBS patients in order 255to test the effects of a more dorsal contact, a more ventral contact, the 256optimal contact and OFF stimulation (i.e., four settings in total). They 257258observed no effects of this manipulation on VF, but they did observe a 259decline between baseline and follow-up in phonemic VF in the STN group across all four settings (which was greater than the GPi group, 260but the contrast did not reach their predefined p < 0.025 level of signif-261262icance). On the basis of observing the non-significant worsening of VF 263also in the OFF stimulation condition, the authors suggested an insertion effect rather than stimulation per se as the cause of this decline. Howev-264er, based on a subset of the STN-DBS patients from the very same cohort, 265 Okun's group [41] subsequently reported on correlations between vol-266ume of tissue activated (VTA) and phonemic VF decline. Here, stimula-267tion of larger ventral parts of STN was correlated with worse VF 268performance [41]. And in a further follow-up study on the GPi-DBS pa-269tients, Okun's group [19] showed that stimulation region did not affect 270VF performance in a subset of the GPi-DBS patients [19], who also did 271272not show any significant declines in VF after DBS.

Furthermore, the patients included in COMPARE trial and reported 273 by Okun et al. [46], as well as by Mikos et al. [41] and Dietz et al. [19], 274 were all unilaterally implanted with either STN-DBS or GPi-DBS. 275 Hence, testing stimulation of different contact positions with bilateral 276 stimulation could potentially have greater effect on VF performance 277 than those reported by Okun et al. [46]. 278

Ehlen et al. (2014) found that STN-DBS PD patients' changes in VF 279 performance between ON and OFF stimulation correlated with elec- 280 trode location and stimulation amplitude. Better VF performance in 281 ON than OFF was associated with more antero-medial positions and 282 higher stimulation amplitudes, which suggests at least some active 283 component in the stimulation itself. We note, however, that this sug- 284 gested effect of the stimulation itself was beneficial to VF performance, 285 rather than detrimental. And since the study did not include any baseline measurements of the patients' VF performance before surgery, it is difficult to know how these beneficial effects of stimulation were related to any potential worsening of VF performances compared to presurgery baseline. 290

Finally, York et al. [83] also found correlations between VF declines 291 and electrode locations of variable kinds. More superior and lateral loca-292 tions in the left hemisphere seemed to be associated with greater pho-293 nemic VF declines. In the right hemisphere, greater phonemic VF 294 declines were associated with electrodes located more posterior and su-295 perior, but laterally closer to STN. And greater semantic VF declines 296 were correlated with more superior locations in the right hemisphere.297 These results are not straightforward to interpret as they rely on a mul-298 titude of correlations with a relatively small sample size, but they still 299 suggest associations between electrode locations and the observed VF 300 declines. 301

The available evidence on effects of electrode locations on the ob- 302 served worsening of VF after DBS is still preliminary and inconclusive. 303 But when detailed VTA-modeling is taken into account as in Mikos 304 et al. [41], or decliners are compared to stable performers in a volumetric space as in Witt et al. [75], electrode positions do seem to play a role in VF decline following DBS – in STN, at least. 307

### 4.4. Stimulation vs. Surgery

Even though the evidence is not overwhelming, the correlations be-309 tween electrode locations and the observed VF declines suggest that either the stimulation itself or insertion effects from the surgery may 311 affect VF performance after DBS in STN. Unfortunately, the sparse literature on this matter is inconclusive, but it does seem to suggest that both the stimulation and the surgery itself may have effects on the observed worsening of VF after DBS. 315

Wojtecki et al. [77] showed that the frequency of stimulation of STN 316 had opposite effects on motor symptoms and verbal fluency in PD pa-117 tients. Low frequency stimulation at 10 Hz improved VF performance 318 while worsening the motor symptoms compared to the typical high frequency stimulation at 130 Hz, which improved motor symptoms while worsening VF performance. This suggests an active role of the stimulation frequency, and by extension the stimulation itself, in the VF performance of STN-DBS-treated PD patients. 323

However, in a more recent open label RCT study, Okun et al. [45] 324 employed a study design with a delayed DBS activation group as control 325 group. 25% of the implanted patients were randomly assigned to a control group where the DBS would not be turned on until 3 months after 327 surgery. Interestingly, the authors found that both groups showed 328 worsening of phonemic and semantic VF after 3 months, a worsening 329 that was sustained after 12 months in both groups. This evidence, on 330 the other hand, strongly suggests an effect of surgery, rather than 331 stimulation. 332

When it comes to testing ON and OFF stimulation effects on VF per- 333 formance, one study has shown significant differences in VF perfor- 334 mance between ON and OFF stimulation with worse performance 335 during ON [57], supporting the notion of an active role of the 336

308

# **ARTICLE IN PRESS**

337 stimulation. In contrast to this, as already mentioned Okun et al. [46] did 338 not observe any significant differences between ON and OFF stimulation, despite a general VF decline with STN-DBS after surgery, suggestive 339 340 of an insertion effect from surgery rather than the actual stimulation. And yet the few other studies that have tested ON and OFF stimulation 341 in relation to VF show mixed results between phonemic and semantic 342 VF but with incomplete reporting (e.g., lack of baseline, use of test com-343 posite scores, lack of tests on the relevant contrasts) due to which we 344 345 cannot fully assess the similarity of the observed VF declines or lack 346 thereof during ON and OFF stimulation [20,28,43,50].

Smith et al. [61] addressed the potential effects of microlesions from
a different angle by using the number of micro-eletrode (MER) passes
during surgery as an index of the extent of the microlesion in STN
from the surgery, and they did not find any significant correlations between the number of MER passes and the phonemic VF decline after
DBS.

Common to the few studies reporting no difference in VF perfor-353 mance during ON and OFF stimulation - and hence suggesting insertion 354effects - is that their evidence is based on negative results. But such null 355results do not provide very conclusive evidence since the absence of 356 evidence is not evidence of absence. Equivalence testing [54,58] or 357 Bayesian statistics [18,33], on the other hand, provide statistical frame-358 359 works that allow the researcher to interpret such null results in a more 360 systematic and meaningful manner.

Furthermore, most of the studies testing ON and OFF stimulation ef-361 fects only allowed 10-30 min before starting neuropsychological testing 362 after turning OFF the stimulation [46,50,77], or do not report how long 363 364 they waited [20,28,43,57]. This is a relatively short interval considering that the cardinal PD motor symptoms vary between a few minutes and 365 several hours in how quickly they are alleviated/reappear after turning 366 367 ON/OFF the DBS [65]. With a similar design studying response inhibi-368 tion, Hershey et al. [26] observed differences between unilateral activa-369 tion of a more dorsal and more ventral contact during a Go/NoGo-task after waiting at least 42 min between change of stimulation settings 370 and testing. Hence, when employing the ON vs. OFF stimulation design, 371 or when testing the effect of stimulation in different active contacts, it 372373 may be advisable to wait at least 45 min [26], and perhaps even 2 h considering the motor symptoms [65], before testing VF or other neuropsy-374 chological measures. 375

Thus, it is still unclear from the literature to what extent the observed VF declines after DBS are caused by insertion effects from the surgery or caused by the actual stimulation itself. But nonetheless, stimulation and insertion effects in combination with electrode locations are those of the suggested mechanisms behind the VF decline that show the strongest associations with the observed worsening of VF after DBS.

382 4.5. Patient Inherent Risks for VF Worsening

This focused review deals with the reported VF worsening after DBS, i.e., in the PD patient cohorts that are screened and found eligible for DBS and who then receive the treatment. This means that it does not deal with the potentially increased risks for VF worsening (and other cognitive declines) in PD patients that are deemed too old or too cognitively impaired to receive DBS.

Results from two RCT studies [15,60] have suggested that advanced 389age, low levodopa response and higher levodopa equivalent dose (LED) 390 391 at baseline were associated with cognitive decline after DBS. However, as noted by Daniels et al. [15], their three factors (higher age, higher 392 LED and higher axial subscore on UPDRS-III at baseline) only explained 393 about 23% of the variance in the cognitive decline after DBS. Further-394 more, both studies made use of composite scores for their measures of 395cognitive decline, and their results are therefore not directly transferra-396 ble to the reported VF worsening after DBS, which is of focus in this 397review. 398

And importantly, both the aforementioned meta-analyses of VF worsening after DBS by Parsons et al. [48] and Combs et al. [12] reported that none of the investigated risk factors were related to VF worsening401after DBS. Parsons et al. [48] tested age, disease duration, stimulation pa-402rameters, and LED change after surgery as moderators of the VF decline.403Combs et al. [12] tested age, disease duration, LED at baseline, and404UPDRS score off medication at baseline in relation to the reported VF405worsening. Hence, it does not seem that any of the potential patient in-406herent risks in the DBS-treated PD cohorts can account for the observed407VF worsening after surgery.408

#### 5. Heterogeneity in Prevalence

As already alluded to, there is considerable heterogeneity in the 410 prevalence of the worsening of VF after DBS. It seems that a subset of 411 patients (10–40%) are often driving the reported group effects of VF 412 decline [7,14,31].

Unfortunately, far from all studies report proper assessments of this 414 individual variation, e.g., reliable change indices (RCIs; [27,67]), but the 415 studies that do include RCIs for pre- and post-surgery evaluations all re- 416 port a small but substantial subgroup of patients with reliable declines, 417 whereas the rest of the DBS patients experience no reliable difference in 418 VF or maybe even a slight improvement. Williams et al. [72] reported 419 that 26% and 29% of STN-DBS PD patients showed reliable declines in 420 phonemic and semantic VF, respectively. The same numbers for their 421 GPi-DBS group were 11% and 29%, respectively. Witt et al. [75] reported 422 that 23% and 39% of STN-DBS PD showed reliable declines in phonemic 423 and semantic VF. Rothlind et al. [55] reported that, across both groups of 424 STN- and GPi-DBS, 16.5% and 11% showed reliable declines in phonemic 425 and semantic VF. And they observed no differences in prevalence be- 426 tween the two groups. York et al. [82] reported that 26.1% and 40% of 427 STN-DBS PD showed reliable declines in phonemic and semantic VF. Fi- 428 nally, Zahodne et al. [84] also referred to an observation of heterogene- 429 ity in VF declines following unilateral DBS. 430

To the best of our knowledge, this relatively large degree of individ- 431 ual variation has not received any thorough and systematic attention. 432 And yet it seems that what is consistently reported as a group effect, is 433 mainly driven by a small subgroup of the DBS-treated patients. In our 434 view, this heterogeneity in prevalence seems to hold promising explanatory potential for the worsening of VF after DBS if properly characterized and investigated. 437

### 6. Possible Underlying Mechanisms

As previously mentioned, VF involves several cognitive processes re- 439 lated to linguistic and executive functioning, in particular [24,25,35,59]. 440 By the use of interference tasks, neurocognitive models have focused on 441 contrasting phonemic and semantic VF performance in an attempt to 442 ascribe them to frontal lobe (executive functioning) and temporal lobe (lexical search) processes, respectively [39,44]. 444

Lesion studies have refined this proposed dissociation between pho-445 nemic and semantic VF. In a meta-analysis on VF performance after focal 446 cortical lesions, Henry & Crawford [25] showed that frontal lesions affected phonemic and semantic VF to similar extents, whereas temporal 448 lobe lesions affected semantic VF more than phonemic VF, suggestive of 449 a shared frontal lobe component in both phonemic and semantic VF. Furthermore, Chouiter et al. [10] recently investigated VF performance 451 in 191 patients with traumatic brain injury (TBI) and managed to also 452 include patients with brain lesions in subcortical structures. This allowed them to show that basal ganglia structures, including putamen, 454 caudate nucleus, and globus pallidus, were integral to both phonemic 455 and semantic VF, which is in line with the reported effects of DBS in 456 STN (and GPi) on VF in PD patients. 457

To add to this, Troyer et al. [66] suggested on the basis of their study 458 of patients with focal brain lesions that the contributions of frontal-lobe 459 and temporal-lobe processes were related to switching and clustering, 460 respectively, both of which are subprocesses of VF and not specific to 461 phonemic or semantic VF. Recently, Vonberg et al. [68] analyzed clusters 462

## **ARTICLE IN PRESS**

and switches during VF performance with DBS ON and OFF. Here, they 463 showed more switches (and marginally shorter switch times) during 464 DBS ON compared to DBS OFF, but with no significant differences in 465 466 the total number of words between ON and OFF. The authors interpret these results to suggest that STN-DBS may subtly increase cognitive 467 flexibility in PD patients. However, due to no baseline evaluations it is 468difficult to fully assess the role of the increased number of switches in 469 relation to potential worsening of VF after DBS. Further supporting our 470 471 observation of considerable heterogeneity in the prevalence of VF worsening, the authors' inclusion of data on the individual patients' VF per-472 473formances in the supplementary material confirmed substantial individual differences in the degree to which patients performed better 474475or worse during DBS ON or OFF.

476 Very tentatively, the limited evidence from the literature seems to suggest that STN (and GPi) may be involved in VF performance through 477a basal-ganglia-thalamocortical network [29,64] involving mainly dor-478solateral prefrontal cortex (dlPFC, BA 9, 46) and left inferior frontal 479gyrus (1-IFG, BA 44-45) at the cortical level as is suggested by the few 480 available PET studies on VF in DBS-treated PD patients [31,57]. This 481 subthalamo-frontocortical connection is further supported by a recently 482 published study by Wojtecki et al. [76] combining recordings of local 483 field potentials (LFP) in the STN through externalized DBS electrodes 484 485 and EEG scalp recordings. Preliminary results from five PD patients 486 demonstrated enhanced coherence between STN and frontal cortex in the low-frequency bands (alpha-theta, 5-15 Hz) during a verbal gener-487 ation task [76]. 488

#### 489 7. Directions for Future Research

Crucially missing from this present overview is more evidence on 490 the effects of stimulation itself and surgery on the reported VF worsen-491 492ing after DBS, as well as on the effects of electrode locations. These aspects entail comparing VF performance during both ON and OFF 493494stimulation conditions at follow-up compared to baseline, as well as relating the potential worsening to detailed VTA-modeling in the individ-495ual patients. A few studies have already employed ON/OFF testing 496 including baseline measurements, but this holds for only one of the 497 498 RCT studies [46]. The total number of such studies does not warrant a meta-analysis as of yet. Hence further studies implementing this study 499design are needed. And in this regard, more studies making use of the 500design introduced by Okun et al. [45] with a delayed DBS activation 501group would allow for further assessments of the potential chronic ef-502fects of stimulation which cannot be assessed with an ON/OFF design 503with relatively short OFF periods (minutes or a few hours). 504

Furthermore, only very few studies have tested the effects of stimulation while patients were also OFF medication, which is the most optimal way to directly target an actual stimulation effect. Finally, evidence from such study protocols in terms of 'no significant differences' between the two conditions is not sufficient in this regard. Equivalence testing or Bayesian inference should be used to address and interpret such potential null results more meaningfully.

512Regarding the heterogeneity of the prevalence of VF declines among 513DBS-treated PD patients, this has not received sufficient attention, why we recommend this aspect to be taken into account in future studies, es-514pecially in combination with more detailed VTA-modeling. In this re-515gard, it may not be sufficient to merely compare stimulation in 516517"dorsal" and "ventral" contacts (as in [46]) in order to account for the potential effects of electrode location and stimulation. Anatomical 518 considerations concerning both cortical projections (the hyperdirect 519pathway from frontal cortex) and subcortical basal ganglia (BG) con-520nections to and from the ventro-medial part of STN (referred to as the 521'associative' subregion) would be of great value in this context. The tra-522ditional view of STN anatomy and function divides it into three separate 523regions, the motor, associative and limbic regions [37]. However, recent 524primate studies using anterograde tracers suggests noticeable overlaps 525between these three subsections [4,23] in addition to a high degree 526

of variation in the overall size and position of the STN in PD patients 527 [16,52]. 528

Recent methodological advances in both acquisition and processing 529 of diffusion-weighted MRI (DWI) allow us to non-invasively map the 530 structural networks of the brain with a newfound precision [30,62]. 531 Such diffusion-based tractography has already been used to examine 532 the tissue and pathways targeted in DBS treatment [6,49]. These ad- 533 vanced techniques allow for detailed delineation of the connections be- 534 tween the STN (and GPi), cortex and other BG structures at the 535 individual patient level. Several studies in healthy adults have demon- 536 strated how the STN subsections and overlaps can be delineated using 537 tractography [1,2,34,51]. Implementing state-of-the-art tractography 538 methods, combined with VTA-modeling, may allow detailed explora- 539 tion of the neural pathways stimulated with DBS in individual patients. 540 Further integrating these methodological advances with measures of 541 behavior and neurophysiology (such as VF performance and M/EEG re- 542 cordings) provides a clear avenue for advancing our knowledge of the 543 mechanisms of DBS and its potential role in the observed worsening 544 of VF after DBS. 545

In relation to potentially mapping the neural pathways stimulated 546 with DBS in the individual patient, the few functional neuroimaging 547 studies on VF and DBS in PD using PET [31,57] have shown correlations 548 between reduced activity in left inferior frontal gyrus (IFG) and (left) 549 dorsolateral prefrontal cortex (dIPFC) and worsening of VF as an effect 550 of STN-DBS. The sparse neuroimaging evidence thus supports a more 551 active role of the stimulation itself in the VF decline where STN-DBS 552 may affect this frontal network through its indirect connections to thal-553 amus via GPi [3,47,64], or antidromically via the hyperdirect pathway 554 connecting the prefrontal cortex directly to STN [29]. The observed 555 worsening of VF after GPi-DBS could potentially be attributed to similar 556 network via thalamus, but more studies are still needed in order to asses how reliably VF is negatively affected by DBS in GPi.

#### 8. Conclusion

Based on recent and earlier meta-analyses, there is reliable evidence 560 for a worsening of both phonemic and semantic VF after DBS. This pri-561 marily pertains to STN-DBS since the number of available studies on 562 the cognitive sequelae of GPi-DBS is still too low for drawing reliable 563 conclusions. The effect sizes of the VF worsening are moderate in size, 564 which seems to be tolerable at the group level, but these tolerable effect 565 sizes may also be reflective of more debilitating effects in a subgroup of 566 PD patients with DBS. 567

There is no clear impression of the possible underlying mechanisms 568 from the literature, but with evidence from PD control groups on best 569 medical treatment (BMT) in two large-scale RCT studies, disease progression does not seem to be able to account for the worsening of VF 571 in DBS patients. Also, DBS-related reductions in dopaminergic medication (mainly in STN-DBS patients) cannot account for the VF decline. 573

Hence, it seems that either surgery or stimulation itself or both to-574 gether in combination with the electrode positions are driving factors.575 However, the evidence in this relation is inconclusive and sparse. The few studies that include detailed VTA-modeling seem to suggest an active role of the stimulation, at least in STN-DBS. But at the same time, the few studies testing VF performance during ON and OFF stimulation failed to find significant differences between the two conditions, tentatively suggestive of an insertion effect from the surgery, rather than stimulation itself. Hence, more studies are needed before a systematic meta-analysis can be conducted. 583

Finally, we have highlighted an aspect of the literature that has not 584 received systematic attention to date, namely a large degree of hetero-585 geneity in the incidence of VF declines following DBS (in both STN and 586 GPi). We speculate that individual variation in cortical and subcortical 587 connections to and from STN and/or GPi may contribute to this 588 heterogeneity. Hence, the application of advanced tractography in 589

559

6

A. Højlund et al. / Computational and Structural Biotechnology Journal xxx (2016) xxx-xxx

combination with detailed VTA-modeling may provide new insights 590 into the role of stimulation effects vs. effects of surgery. 591

Our recommendations for future studies on VF include optimizing 592 593study designs to include both ON and OFF stimulation as well as baseline measures, calculating reliable change indices (RCI) for neuro-594psychological results, and acquiring diffusion-weighted MRI on patients 595for tractography of cortical and subcortical connections to and from 596STN/GPi. 597
