We describe the case of a 63-year-old woman with aneurysm of the descending aorta who initially underwent intravascular stent grafting of the descending thoracic aorta followed by coil embolization, as well as additional cuff placement at the very proximal portion of the stent, to treat a pseudoaneurysm at the proximal stent margin. The stent graft was covering the subclavian artery, and therefore her left radial artery pulse was weakened, although it remained patent because of retrograde back flow. Figure 1 shows the proximal end of the stent covering the left subclavian artery and partially covering the left carotid artery. The patient returned to the hospital with severe left-sided chest and back pain. Radiographic studies demonstrated an aneurysm surrounding the distal limb of the stent graft with thrombus extending around the stent into the aneurysmal sac, with a short distance between the aneurysm and celiac artery that was inadequate for landing an additional stent between the previous thoracic stent and the celiac trunk. Therefore the patient underwent open repair.

A left posterolateral thoracotomy was made at the level of the eighth intercostal space. The incision was extended into the abdomen, the abdominal fascia was dissected out, and the diaphragm was taken down radially with an endo-GIA stapler (US Surgical, Tyco Healthcare, Norwalk, CT) approximately 3 cm from the chest wall. Cardiopulmonary bypass was initiated through the left femoral vessels. A crossclamp was applied on the distal aorta, followed by clamping of the aneurysm with the stent graft within. The aorta was opened, and after the back bleeding from the celiac artery was noted, this was clamped individually. A 26-mm graft was then anastomosed in an end-to-end fashion to the distal aorta just above the celiac trunk. A clamp was placed on the graft, and the distal aortic clamp was released to resume perfusion to the celiac artery. After 1 cm of distal stent was resected, the proximal anastomosis was then performed in an end-to-end fashion from the graft to the endograft, with the patient’s native aortic wall incorporated into the suture line peripheral to the endograft. Figure 2 illustrates the operative steps. There were no perioperative or postoperative complications, and the patient was discharged home on postoperative day 7.
Discussion
Endoleak is relatively common and the most disappointing complication of stent graft treatment of aortic aneurysm.\textsuperscript{1–3} Even in the absence of an endoleak, the aneurysm might continue to enlarge. The pathogenesis of this phenomenon remains unclear,\textsuperscript{4} and therefore surveillance after endovascular stent placement must include regular evaluation of aneurysm size or aneurysm volume. Aneurysm sac enlargement without an endoleak is not a benign condition.\textsuperscript{4} Sakai and colleagues\textsuperscript{5} reported that the caliber of the aneurysm continued to increase compared with its diameter at computed tomography immediately after stent graft placement in 30\% of patients without evidence of perigraft leak. Recurrent or persistent pressurization of the aneurysmal sac will eventually result in rupture. Furthermore, continued expansion of the aneurysmal sac can result in dilatation of the aorta and threaten the integrity of the proximal and distal anastomotic seals.\textsuperscript{4} An enlargement of the aneurysm after treatment indicates a failure of the procedure.\textsuperscript{4} In case of endotension and a growing aneurysm, an open operation and placement of a regular vascular graft should be considered.\textsuperscript{4}

Conclusion
A continuous aneurysmal dilation of the aorta after endovascular stent placement should be managed with open repair if an endovascular approach is not feasible.
