Meta-analysis

A B S T R A C T

Background: Victims who are involved in a compensation process generally have more health complaints compared to victims who are not involved in a compensation process. Previous research regarding the effect of compensation processes has concentrated on the effect on physical health. This meta-analysis focuses on the effect of compensation processes on mental health.

Method: Prospective cohort studies addressing compensation and mental health after traffic accidents, occupational accidents or medical errors were identified using PubMed, EMBASE, PsychInfo, CINAHL, and the Cochrane Library. Relevant studies published between January 1966 and 10 June 2011 were selected for inclusion.

Results: Ten studies were included. The first finding was that the compensation group already had higher mental health complaints at baseline compared to the non-compensation group (standardised mean difference (SMD) = −0.38; 95% confidence interval (CI) −0.66 to −0.10; p = .01). The second finding was that mental health between baseline and post measurement improved less in the compensation group compared to the non-compensation group (SMD = −0.35; 95% CI −0.70 to −0.01; p = .05). However, the quality of evidence was limited, mainly because of low quality study design and heterogeneity.

Discussion: Being involved in a compensation process is associated with higher mental health complaints but three-quarters of the difference appeared to be already present at baseline. The findings of this study should be interpreted with caution because of the limited quality of evidence. The difference at baseline may be explained by a selection bias or more anger and blame about the accident in the compensation group. The difference between baseline and follow-up may be explained by secondary gain and secondary victimisation. Future research should involve assessment of exposure to compensation processes, should analyse and correct for baseline differences, and could examine the effect of time, compensation scheme design, and claim settlement on (mental) health.

© 2011 Elsevier Ltd. Open access under the Elsevier OA license.

Victims who are involved in a compensation process generally have a worse recovery than victims who are not involved in a compensation process.1–5 This hampered recovery of victims who claim monetary compensation for the injuries, costs and losses relating to an accident is often explained by the theory that being involved in claims settlement creates an unconscious financial incentive for victims not to get better as long as the settlement lasts (secondary gain).6 Another explanation is that the compensation process is a stressful experience7: victims suffer from renewed distress (secondary victimisation)8 caused by the claims settlement process.

Previous research regarding the effect of compensation has concentrated on investigating the effect on physical health, such as the level of pain, disability, disease symptoms, and (more indirectly) return-to-work. Several systematic reviews were conducted regarding the correlation between compensation and physical well-being9–11 and also a systematic meta-review has been performed over 11 systematic reviews that all concern the effect of compensation on physical health.12 Although most studies found an association between compensation and poor health outcomes, the quality of the existing evidence on the association between compensation and worse health outcomes has become the subject of debate.13–15

In contrast to physical health, few studies investigated the association between compensation procedures and mental health. Similar to physical health, most studies measuring mental health found that victims who are involved in compensation claims had higher levels of depression, anxiety and post traumatic stress...
disorder (PTSD) than non-compensated victims.\textsuperscript{16–18} However, another study did not find a relation between compensation procedures and mental health.\textsuperscript{19} To be able to draw a general conclusion about the effect of compensation procedures on mental health of trauma victims, we conducted a systematic review and meta-analysis. To our knowledge, no meta-analytic study has yet investigated the overall effect of compensation on mental health. Considering the negative effect of the compensation procedure on physical health and the fact that the compensation procedure can be stressful, we hypothesised that victims involved in a compensation process have higher mental health problems compared to victims who are not involved in a compensation process.

**Method**

**Study selection**

A literature search was conducted using five electronic databases: PubMed, EMBASE, PsycINFO, CINAHL, and Cochrane library on studies published from 1966 to 10 June 2011. No language restrictions were applied. Search terms included compensation, workers’ compensation, or litigation, combined with empirical study designs, i.e. epidemiological, clinical, cohort, longitudinal, follow-up, prospective, retrospective studies or meta-analysis, combined with type of accidents, i.e. traffic accidents, occupational accidents, or medical errors. We also included whiplash injuries, because this injury could be associated with traffic accidents without specifically mentioning the accident. Various synonyms were used for each concept. We used subject heading terms when available. The exact search strategy is available from the authors.

Eligible studies were selected in three steps. First, titles and abstracts were screened and studies were excluded if title and abstract did not meet any of the following inclusion criteria: (1) participants were injured by traffic accidents, occupational accidents, or medical errors; (2) some participants were involved in a compensation process; (3) some other participants were not involved in a compensation process; (4) outcome measure was mental health related (e.g. depression, anxiety, or PTSD); (5) type of study was a follow-up design with at least two measurements (baseline and follow up). In the second step, we retrieved full text articles of the remaining studies. Studies were excluded if they did not fulfil the inclusion criteria mentioned above. We excluded according to the following order: (1) outcome, (2) non exposed group (i.e. non-compensation group), (3) study design, (4) type of accident, and (5) exposed group (i.e. compensation group). If a study was excluded based on one criterion, then the remaining criteria were not investigated further. Finally, we searched the reference lists of the included studies to find additional publications. The study selection was conducted independently by two investigators (NE and LH). Disagreements were resolved by a third investigator (DB).

**Data extraction**

We extracted information about the number of participants at the start of the study, percentage of males, average age, type of accident, and type of injury. Furthermore, we collected information about the recruitment setting, country, the kind of compensation system (i.e. third party, no fault, worker’s compensation, litigation), and we calculated the percentage of participants who were involved in a compensation process (versus not involved in compensation). In addition, we extracted when the baseline and follow-up measurements were conducted, the percentage of participant drop-out, the mental health instruments, and all mental health outcome data. If studies did not report sufficient data or dichotomous data only, authors of these studies were contacted. If studies did not report standard deviations, we calculated the standard deviations according to guidelines in the Cochrane handbook.\textsuperscript{20} Finally, we investigated whether studies reported significant differences between cohorts regarding gender, age, education, occupational status before injury, injury severity, and mental health/psychopathology before injury. Data extraction was performed by the primary investigator (NE) and randomly checked by another investigator (DB).

**Quality assessment**

We used the Newcastle Ottawa Scale (NOS)\textsuperscript{21} to assess the quality of the included studies. The scale is praised for its simplicity of use.\textsuperscript{22} A disadvantage is its unknown validity.\textsuperscript{22} We chose this scale because it was recommended for evaluation of cohort studies by the Cochrane Handbook.\textsuperscript{20}

We slightly modified the NOS for this review. We interpreted the item about the representativeness of the exposed cohort as a question about whether the researchers recruited their participants from a valid setting and whether all eligible participants were equally approached to participate. The item about whether the outcome of interest was present at the start of the study was removed. This was done because we wished to investigate whether there is a difference in mental health rather than examining the presence of a disease or not. Because we removed this item, our NOS contained seven questions.

Furthermore, the item about comparability of cohorts asked for two important factors which need to be equal in both cohorts to be able to compare the cohorts. We decided the most important factors to be: (1) mental health at baseline, because the outcome measure needs to be equal at baseline to draw conclusions about the follow up, and (2) gender, because being female is one of the best predictors of depression, anxiety\textsuperscript{23} and PTSD prevalence.\textsuperscript{18,24} The length of follow-up needed to be at least three months, as three months is the median time for recovery from depression\textsuperscript{25} and it is also the average time needed to recover from PTSD.\textsuperscript{26} Finally, we decided that the loss to follow-up needed to be less than twenty percent.\textsuperscript{27}

The NOS uses a star system to allow a visual semi-quantitative assessment. High quality studies are awarded a maximum of one star for each item than can be answered affirmatively, except for item 4 to which a maximum of two stars can be allocated. The quality of the studies was assessed independently by two reviewers (NE and DB).

**Data analysis**

First, we analysed the baseline measurement to investigate whether victims who start a compensation procedure have a similar mental health score at baseline as victims who are not involved in a compensation process. We calculated the pooled standardised mean difference (SMD) and 95% confidence intervals (CI) of the total mental health by adding the various mental health outcomes together. When a study included multiple mental health measures, a combined effect size was calculated. If anxiety, depression or PTSD was higher in the compensation group than in the non-compensation group, we indicated the effect direction to be negative. For studies measuring SF MCS, the effect direction was negative if the SF MCS was lower in the compensation group than in the non-compensation group. A negative effect size indicates that injury victims who are involved in compensation process have more mental health complaints at baseline compared to non compensated victims. The one-study removed analysis was conducted to show the impact of each study on the combined effect. We performed subgroup analyses in which we removed studies with baseline measurements other than directly after the
accident. Besides the total mental health, we also calculated the SMDs of the separate mental health outcomes (e.g. depression, anxiety, and PTSD).

Second, we examined the effect of compensation on mental health by calculating the difference between the baseline-post change score of the compensation group and the baseline-post change score of the non-compensation group. To be able to compute the SMD of this difference between the change scores of the compensation group and the non-compensation group, the correlation between the time points is necessary. As no study reported this correlation, an estimate of the correlation \( r = 0.90 \) was used.\(^{28}\) A negative effect size indicates that the compensation group has a smaller increase of mental health compared to the non-compensation group. Similar to the analysis of the baseline measurement, we calculated the pooled SMD effect size of the total mental health and we performed a one-study removed analysis. Subgroup analyses were conducted on studies clusters with similar post measurement time points. Finally, we examined the SMDs of the separate mental health outcomes.

We chose a random effects model for all analyses because studies were methodologically diverse. An effect size of 0–0.32 is considered to be small, 0.33–0.55 is moderate, and 0.56–1.2 can assumed to be large.\(^{29}\) Statistical heterogeneity was assessed by calculating the Q-statistic and the I\(^2\)-statistic. A significant Q-statistic rejects the null-hypothesis of homogeneity. An I\(^2\) value of 0% indicates no observed heterogeneity, 25% is low, 50% is moderate, and 75% is high heterogeneity.\(^{30}\) Publication bias was tested by inspecting the funnel plot. Publications bias is present when studies with a positive effect are published whilst small studies with no effect remain unpublished. A possible publication bias is indicated by an asymmetric funnel plot showing a relationship between the effect size and the standard error.\(^{20}\) Comprehensive Meta-Analysis software (version 2.2.057) was used for all analyses.

Furthermore, the clinical relevance of the study results was assessed. Because the included mental health outcomes have a different scale range, all means were re-calculated into a scale ranging from 0 to 10. We then calculated the difference at baseline and the difference between the pre-post change of the compensation group and the non-compensation group, which was expressed in a percentage. A difference of at least \( 10\% \) indicates a clinically relevant difference.\(^{20}\)

The quality of evidence was examined by the GRADE approach as recommended by the Cochrane handbook.\(^{20}\) Establishment of the quality of evidence involved consideration of (1) study design and risk of bias, (2) directness of evidence, (3) homogeneity or consistency of results, (4) precision of results (small confidence intervals), and (5) publication bias. The GRADE approach specifies four levels of quality: high, moderate, low, very low. Quality of evidence is considered to be high if the included studies fulfill all five factors described above. The quality of evidence is downgraded one, two or three levels if respectively one, two or three of the following limitations apply: (1) limitations in study design, i.e. lack of allocation concealment, lack of blinding, large attrition, selective reporting of outcomes, (2) indirect evidence, e.g. studies address a restricted version of the main review question in terms of population, intervention, control or outcome, (3) heterogeneity without robust explanation, (4) imprecise results, when studies include few participants and have wide confidence intervals, i.e. CI's larger than 0.60, (5) high probability of publication bias.

## Results

### Study selection

A total of 2634 references were identified using the electronic databases: 700 in PubMed, 1231 in EMBASE, 366 in CINAHL, 294 in PsycINFO, and 43 in Cochrane library. After exclusion of 669 duplicates, the 1965 remaining titles and abstracts were inspected. Of the 1965 references, we excluded 1874 based on the information presented in the titles and abstracts. Of the remaining 91 references, full text articles were retrieved. Three references could not be examined because the full text versions could not be retrieved.\(^{31–33}\) Furthermore, 71 articles were excluded: 37 did not report a mental health outcome measure, sixteen did not include a non-compensation group, 15 were no prospective cohort study, and two studies did not concern traffic, occupational or medical accidents. Seventeen studies were found to meet our inclusion criteria. Not all 17 selected papers could be included in the meta-analysis: two studies were excluded\(^{14,35}\) because they were based on the same original sample as a third study.\(^{17}\) One study was excluded after contacting the authors because it turned out that the study measured mental health only once.\(^{2}\) Six studies were excluded because not all necessary data were provided in the article and the missing data were not retrieved after contacting the authors.\(^{36–41}\) No additional articles were found after reference search. However, we added two articles that were found in the reference lists of other articles that we read in preparation of this research.\(^{42,43}\) These two articles were not selected by our search strategy because the type of accident was not specified in title and abstract. In total, ten studies were included in our meta-analysis. The flow chart of the study selection is displayed in Fig. 1.

### Study characteristics

The included studies were all (observational) prospective cohort studies. The total number of participants was 3936, varying from 95 to 1059. Percentage of male gender was 33–100%. Average age ranged from 31.1 to 46.8 years old. Six studies investigated victims of motor vehicle accidents, three studies included victims with injury following various kinds of accidents, and one study investigated back pain caused by work accidents. Six studies were conducted in Australia, two in the USA, and two in the UK. Three studies examined participants who were involved in no fault compensation processes (one of these no fault studies explicitly excluded workers’ compensation claims), two studies reported that compensation claims were settled according to a third party compensation system (one of the studies included public liability and worker’s compensation), four studies included participants in litigation (one of the litigation studies dealt with common law litigation in combination with workers’ compensation), and finally...
one study only mentioned to deal with ‘compensation claims’ without specification. The percentage of participants involved in compensation ranged from 12% to 69%. (Two studies included participants whose compensation was settled.\textsuperscript{17,44} These settled claims were excluded in the calculation of percentage of participants involved in compensation procedures. One study considered a group of private health insurance claims to belong to the compensation group,\textsuperscript{4} but we assigned the health insurance claimants to the non-compensation group, consistent with the current debate on this topic.\textsuperscript{35–47})

Baseline measurement varied from pre-injury status (measured in retrospect) to 6 months after injury and post measurement varied from 3 months to 24 months after baseline. Attrition ranged from 14% to 57%. Five studies measured depression outcomes (BDI, HADS-D, or Zung), four studies had anxiety as outcome measure (HADS-A or STAI-state), seven studies reported PTSD outcomes (CAPS, CIDI, Foa, or IES-R), and two studies examined a mental component score (MCS) of the SF-36 or SF-12. Almost all studies included or provided continuous data except for one study which reported dichotomous data.\textsuperscript{18} The characteristics of the included studies are described in Table 1.

With respect to differences between cohorts, we found that seven studies analysed gender differences between cohorts but none of them found significant differences between cohorts.\textsuperscript{3,4,17,42,43,48,49} Three studies found that the non-compensation group was significantly older than the compensation group,\textsuperscript{3,4,42} whereas four studies did not find age differences.\textsuperscript{17,44,46,48} Two studies showed that the non-compensation group enjoyed a higher education than the compensation group,\textsuperscript{4,48} versus three studies that reported no difference in education level.\textsuperscript{1,42,49} Regarding occupational status, one study showed that the percentage of participants working before the injury was higher in the compensation group compared to the non-compensation group,\textsuperscript{3} versus two studies that indicated non-significant differences in pre-injury working status.\textsuperscript{3,17} Injury severity was found to be similar between cohorts in four studies\textsuperscript{3,17,44,46} and only one study reported that the compensation group contained more severe injuries than the non-compensation group.\textsuperscript{3} Finally, one study reported a lower percentage of past history of psychiatric disorder in the compensation group than in the non-compensation group,\textsuperscript{4} versus two studies that found no difference in previous psychological well-being or psychopathology.\textsuperscript{3,48}

Study quality

The study quality was assessed by the NOS. A maximum of eight stars was allocated to the individual studies. All studies fulfilled the criterion of external validity (item 1): all studies recruited their participants from a valid setting (mostly trauma hospitals, one rehabilitation centre) and all eligible participants were equally approached to participate. All non-compensation groups were recruited from the same population as the compensation group (item 2), although in one study the compensation group consisted of work related back pain whereas the non-compensation group consisted of people who were injured outside the workplace.

None of the studies measured the exposure to compensation procedures in an accurate way (item 3). In general, studies just asked their participants whether they were involved in compensation or litigation or had contacted a lawyer. Consequently, the compensation group could also include, e.g., participants with private health insurance claims and victims of crime. Another problem with ascertainment of exposure was that involvement in compensation was often only asked at baseline, whereas it is plausible that some participants switch cohorts during the study (e.g., they drop the claim because they are not eligible or they decide to start compensation later on because they suffer from their injury longer than expected). Thus we could not award stars regarding item 3.

Four studies did not find or corrected for differences regarding both mental health at baseline and gender and thus these studies earned two stars [1,4,8,49] and one study found no baseline mental health difference but did not measure gender thus was awarded one star (item 4). No study was awarded a star for mental health outcome assessment (item 5), because questionnaires were often filled out by the participants themselves rather than by an independent blind physician or record linkage. (Three studies did use a clinical structured interview to ascertain PTSD but the authors did not describe whether the clinician was blind.)

All studies met the criterion of a follow-up of three months or longer (item 6). Finally, only two studies lost less than 20% of participants in the follow-up (item 7). The allocation of stars to the individual studies can be found in Table 2. Considering the unsecure assessment of exposure to the compensation process and the lack of independent blind assessment of mental health, it was found that the overall study quality was limited.

Mental health at baseline

The compensation group had higher mental health complaints at baseline compared to the non-compensation group (SMD = -0.38; 95% CI -0.66 to -0.10; p = .01). The SMD indicated a moderate effect size and the clinically relevant difference was 7.8%. However, heterogeneity was high (Q = 86.6; p < .01; I² = 89.6%). The one-study removed analysis indicated that all studies had a significant impact on the total mental health at baseline, of which the study by Gabbe et al. had the largest impact. Without this study, the mental health difference between compensation and non-compensation increased a little bit compared to the overall difference (SMD = -0.47; 95% CI -0.64 to -0.30; p < .01). Removal of this study somewhat reduced the heterogeneity, but heterogeneity was still significant and moderate (Q = 18.7; p = .02; I² = 57.2%). Forest plot of the overall mental health at baseline measurement can be found in Fig. 2.

Fig. 2. Forest plot of standardised effect sizes of compensation compared to non-compensation at baseline measurement. SE = standard error, LL = lower limit, UL = upper limit.
We further investigated whether subgroup analyses of the different baseline measurements (i.e., pre-injury, directly after the accident, and six months after the accident) could reduce heterogeneity. First, we removed the two PTSD outcomes that were measured not until six months after the accident.43,44 This slightly decreased the difference in mental health between cohorts compared to the overall difference at baseline (SMD = −0.35; 95% CI −0.65 to −0.05; p = 0.02) but heterogeneity was still high (Q = 81.7; p < 0.01; I² = 90.2%). In the second subgroup analysis, the two studies measuring pre-injury baseline scores were removed,3,4 which increased the mental health difference (SMD = −0.54; 95% CI −0.65 to −0.43; p < 0.01) and resulted in a homogenous pooled SMD (Q = 5.1; p = 0.65; I² = 0.0%).

Analyses of the separate mental health outcomes showed that at baseline the compensation group was more depressed (SMD = −0.42; 95% CI −0.69 to −0.15; p < 0.01) and suffered from more PTSD symptoms (SMD = −0.47; 95% CI −0.65 to −0.28; p < 0.01) compared to the non-compensation group. The compensation group was slightly more anxious (SMD = −0.22; 95% CI −0.50 to 0.07; p = 0.13) although this result was not significant. The pooled effect size of the two studies measuring SF MCS showed that the compensation and non-compensation group scored similar on the SF MCS scale (SMD = −0.05; 95% CI −0.84 to 0.75; p = 0.91). Heterogeneity tests for depression (Q = 12.4; p = 0.02; I² = 67.7%), PTSD (Q = 14.0; p = 0.03; I² = 57.1%) and SF MCS (Q = 12.0; p < 0.01; I² = 91.7%) were significant and moderate to high. Heterogeneity test for anxiety (Q = 7.0; p = 0.07; I² = 57.1%) was not significant, but the non-significance was marginal and the I² statistic indicated a moderate observed heterogeneity. We could not perform subgroup analyses on different types of compensation systems because there was too much variety in compensation systems.

**Mental health between baseline and post measurement**

Between baseline and post measurement, the mental health in the compensation group improved less compared to the non-compensation group (SMD = −0.35; 95% CI −0.70 to −0.01; p = 0.05). The SMD was classified to be a moderate difference, although the clinically relevant difference was only 2.3%. Heterogeneity was high (Q = 108.9; p < 0.01; I² = 91.7%). The one-study removed analysis indicated that several studies had a significant impact on the total mental health change, of which the study by Bryant and Harvey44 had the largest impact. Removal of this study resulted in a small increase of the mental health difference between cohorts (SMD = −0.43; 95% CI −0.78 to −0.07; p = 0.02) but heterogeneity was still high (Q = 99.9; p < 0.01; I² = 92.0%). The forest plot of the effect of compensation on mental health can be found in Fig. 3.

We further examined whether subgroup analyses of the three different post measurements (i.e., 6, 12, and 24 months after the baseline measurement) could reduce heterogeneity. First, we analysed the four studies that conducted the post measurement after six months.17,44,49,50 We did not find a significant mental health difference between the compensation group and the non-compensation group between baseline and six months, although there could be a trend of significance that the mental health in the compensation group improved more than the non-compensation group (SMD = 0.33; 95% CI −0.07 to 0.71; p = 0.10). Heterogeneity was moderate (Q = 9.2; p = 0.03; I² = 67.2%). The second subgroup analysis concerned the five studies with post measurements after 12 months.3,17,18,49,50 This analysis revealed that the mental health of the compensation group improved less compared to the non-compensation group, but this difference was not significant (SMD = −0.36; 95% CI −0.91 to 0.20; p = 0.21) and heterogeneity was high (Q = 65.9; p < 0.01; I² = 93.9%). Finally, we examined the effect of compensation after 24 months.42 (A third study also measured PTSD after 24 months, but we did not include this study in the 24 months analyses because their PTSD baseline measurement was conducted after 6 months.)44 We found that compensation did not have an effect on mental health after 24 months (SMD = −0.13; 95% CI −0.29 to 0.04; p = 0.13). The pooled SMD was homogeneous (Q = 0.5; p = 0.49; I² = 0.0%). However, this finding needs to be interpreted with caution considering the fact that this analysis only included two studies. Removal of the pre-injury studies somewhat decreased the difference between pre-post change between compensation and non-compensation group (SMD = −0.26; 95% CI −0.51 to 0.02; p = 0.04) compared to the overall pooled effect size, but it did not reduce heterogeneity (Q = 21.6; p < 0.01; I² = 67.6%).

The analysis of the separate mental health outcomes showed that groups had a similar small decrease in symptoms of depression (SMD = −0.08; 95% CI −0.32 to 0.17; p = 0.55), anxiety (SMD = −0.10; 95% CI −0.45 to 0.24; p = 0.56), PTSD (SMD = −0.23; 95% CI −0.50 to 0.03; p = 0.09), and small increase of well-being measured by SF MCS (SMD = −0.51; 95% CI −1.76 to 0.74; p = 0.42). Heterogeneity was significant and moderate to high for all: depression (Q = 10.0; p = 0.04; I² = 60.1%), anxiety (Q = 10.1; p = 0.02; I² = 70.2%), PTSD (Q = 28.6; p < 0.01; I² = 75.5%) and SF MCS (Q = 29.7; p < 0.01; I² = 96.6%). The results of all analyses are summarised in Table 3.

**Publication bias**

The possibility of publication bias was examined by inspecting the funnel plot. As several studies drew conclusions about the
effect of compensation at post measurement without analysing or controlling for the baseline difference, we studied both the funnel plot of the post measurements (Fig. 4A) and the funnel plot of the differences between pre–post change (Fig. 4B). Visual inspection of the funnel plots indicated that studies with both large and small standard errors were scattered on both sides of the pooled SMD (centre line). However, the plots were not completely normal as some studies did not fit within the guidelines of the plot. Closer inspection showed that the deviant studies in the funnel plot of post measurements (Fig. 4A) were different from the outlying studies in the funnel plot of the difference between pre–post change (Fig. 4B), which was probably caused by high heterogeneity.

**Clinical relevance**

The clinical relevance was determined by expressing the standardised mean difference in terms of a percentage. At baseline, the mean mental health of the compensation group was 7.8% lower than the mean mental health of the non-compensation group. At follow-up, there was a 10.1% mental health difference at the expense of the compensation group. Consequently, between baseline and post measurement, the mental health was found to increase 2.3% less in the compensation group compared to the non-compensation group. Only the mental health at follow-up met the 10% criterion for clinical relevance, but both the difference at baseline and the change between baseline and follow-up were less than 10%, thus were not clinically important. (These percentages should be used with caution because the mental health scales which the percentages are based on are not ratio scales. These percentages were provided as a practical ‘translation’ of the study results.)

**Quality of evidence**

The quality of evidence as assessed by the GRADE approach. First, the quality of study designs (as assessed by the NOS) was limited, i.e. no blind assessment, unsecure exposure, and a majority of studies having a loss to follow up of more than 80%, which implies bias. Additionally, all studies were observational studies, for which we already should downgrade the quality of evidence with two levels. Second, studies used direct outcome measures for mental health and populations were direct related to the research question. Third, the results of the main analyses were heterogeneous because of the variety of measurement points, mental health outcomes, and compensation systems. Fourth, results were probably imprecise as most confidence intervals were larger than 0.60. Finally, there is a possibility of publication bias. In conclusion: based on the five GRADE aspects, the quality of evidence was downgraded to the lowest level.

**Fig. 4.** Funnel plot of the studies investigating the association between compensation and mental health. (A) Post measurement; (B) difference between pre–post measurement.
Discussion

This study investigated the association between being involved in a compensation process and mental health. First, we found that the compensation group had already higher mental health complaints at baseline compared to victims who were not involved in compensation. However, heterogeneity was high. The subgroup analyses revealed that removal of the two studies that conducted a pre-injury baseline measurement removed heterogeneity and increased the mental health difference between compensation and non-compensation group at baseline. Conducting subgroup analyses on the individual mental health outcomes depression, anxiety, and PTSD only removed heterogeneity for anxiety, but the results for depression, PTSD and SF MCS were still heterogeneous.

The second finding was that the mental health between baseline and post measurement increased less in the compensation group compared to the non-compensation group. This finding was consistent with our hypothesis and with previous meta-analyses about the effect of compensation on physical health.\(^5\) Heterogeneity was high. Subgroup analyses of three different post measurements (i.e. 6, 12 and 24 months) somewhat reduced heterogeneity, which may indicate that only similar time frames should be compared. Duration of the compensation process might have an effect on mental health as suggested by Littleton et al.\(^4\) who found that the mental health improved the first six months and deteriorated between 6 and 12 months. Cotti et al.\(^8\) also reported the suffering increased when the compensation process lasted for more than one year, whereas Harris et al.\(^11\) did not find a difference in length of follow-up. However, our subgroup analyses on different post measurements were not significant and the number of studies was small so we could not draw conclusions about the effect of time. Subgroup analyses of the separate mental health outcomes did not reduce heterogeneity.

Although we found significant differences both at baseline and between baseline and post measurement, the findings should be interpreted with caution considering the fact that the quality of evidence was very low because of limited study quality (uncertain assessment of exposure and assessment of outcome), heterogeneity (different compensation systems, outcome measures, and measurement points), imprecision (large confidence intervals), and possible publication bias.

Upon taking a closer look at the mental health differences between cohorts expressed in percentages, i.e. at least 7.8% at baseline, 10.1% at follow-up, and 2.3% between baseline and follow-up, the mental health difference at baseline explained three-quarters of the effect of compensation at post measurement. Considering this large contribution of the difference at baseline, it is remarkable that the previous meta-analyses about the effect of compensation on physical health and also several of the included studies in the current meta-analysis assessed post measurement only, rather than the change between baseline and post measurement. This could imply that the reported effect of compensation in previous meta-analyses and individual studies is overestimated. The health at baseline may be an additional element in the discussion about the quality of the existing evidence on the association between compensation and worse health outcomes.\(^12\)\(^14\)\(^15\)

The mental health difference at baseline may be explained by a selection bias.\(^5\)\(^7\) One study suggested that the compensation group could have more severe injuries than the non-compensation group.\(^4\) However, only one of the five studies which analysed injury severity between cohorts reported more severe injuries in the compensation group.\(^1\) We also did not find a strong indication for cohort differences regarding gender, age, education, working status before injury, or mental health differences/psychopathology before injury, because for each variable we found more studies indicating non-significant differences between cohorts than those indicating significant differences. One study provided another explanation for the mental health difference at baseline: the authors suggested that having decided to start compensation causes victims to portray themselves more distressed at the initial assessment\(^17\); participants might have developed a ‘compensation mindset’ already at baseline. However, another study did not consider early symptom exaggeration to be a plausible explanation for differences at one month after accident; according to this study there is an increased likelihood that litigation has an effect on psychological adjustment rather than the converse being the case (p. 227).\(^43\) The final explanation for the difference at baseline is that the compensation group may experience more anger, frustration and blame about the accident\(^23\); two studies for example showed that the compensation group mainly consisted of car crashes, whereas the non compensation group mainly consisted of falls.\(^3\) More research is needed to investigate the cause of the difference at baseline.

The finding that the mental health between baseline and post measurement improved less in the compensation group compared to the non-compensation group may be explained twofold: most of the included studies suggested that victims in compensation could perpetuate or exacerbate their symptoms because of financial incentive (secondary gain), and all included studies indicated that victims in compensation could be stressed by the compensation process (secondary victimisation).\(^5\) The latter is caused by the numerous assessments\(^49\) and thus repeated confrontation with the traumatic history\(^17\)\(^43\) delayed funds\(^18\) and financial risks, and the often adversarial relationship between client and the insurance agency.\(^43\) In some studies it was also argued that the compensation group could have suffered more severe injuries,\(^52\) severe crashes,\(^3\) previous psychopathology,\(^4\)\(^43\) and psychological vulnerability.\(^46\) However, as we argued with respect to the baseline difference, we did not find a strong indication for differences between groups. Finally, the compensation effect could be explained by confounding variables\(^52\) such as lawyer involvement,\(^2\) or blame, anger and injustice\(^49\) and being ‘not at fault’.\(^53\)

Strengths and limitations

The strength of this study is that this is the first meta-analysis about the association between compensation and health that investigates the difference in health at baseline and the difference between baseline and post measurement. An additional strength is that we assessed the quality of evidence and clinical relevance.

The major limitation of the study is the poor quality of evidence because of limited study quality, heterogeneity, imprecision and possible publication bias. Also we were unable to perform valid subgroup analyses because of the small number of included studies. The final limitation is that we could have missed eligible studies by defining the type of accident in the search strategy.

Implications

The results of this study imply that the legal professionals and psychologist should be alert at the occurrence of mental health problems in victims involved in the compensation process and should realise that these mental health problems may be caused or worsened by a stressful compensation process. Although it is not established whether, to what extent, and which elements of the claims settlement process contribute to mental health problems, this study adds some weight to the arguments made in legal literature for changes to the claims settlement process, e.g. making it less stressful by enhancing client centred claims settlement,\(^54\) information supply, communication\(^55\)\(^56\) and by paying more attention to non-pecuniary needs.\(^57\) Victim support services and
psychologists on their turn could broaden their services by being sensitive to the anti-therapeutic issues that victims could encounter during the compensation process, and by addressing these issues in addition to the ‘regular’ trauma assistance if necessary.28

Future research

More research is necessary to be able to draw a conclusion about the effect of compensation on mental health. First of all, more primary studies with high quality study designs are needed,13 especially with respect to the assessment of exposure to compensation: researchers should thoroughly describe the kind of legal compensation system, including procedures and processes,15 and should accurately determine the involvement in compensation. It might also be interesting to assess whether the compensation for psychological injury is part of the claim, because such a claim element could correlate with mental health outcome. The outcome should preferably be measured at standardised time points: directly after the accident and then ideally at 6, 12 and 24 months after the accident, possibly complemented with an indication of pre-injury health status. Researchers may pay more attention to the comparability of cohorts: it is advisable to analyse differences at baseline and to control for baseline differences in order to allow more solid conclusions about the effect of compensation processes as such. Study designs such as randomised controlled trials are neither ethical nor possible,3 but a potential improvement regarding design would be to create matched controls for the compensation group.11 Large prospective cohort studies are essential.

Second, more research is needed to study which elements of the compensation process may hamper recovery.30 Researchers could further investigate whether compensation process duration has an effect on health as was also suggested by Littleton et al.49 and Cotti et al.5 Also, it could be valuable to conduct more studies across different jurisdictions2 and to compare the elements of the different compensation scheme designs considering the fact that no fault systems were found to be related to better health outcomes compared to third party systems.50,61 Finally, a meta-analysis could be performed to draw a general conclusion about the effect of claim settlement on health as some studies reported that claim settlement improves health,5,62 whereas others do not find a relation between claim settlement and health.17,44,63 More knowledge about which elements of the compensation process impair the health of claimants would enable to improve health of victims involved in compensation processes.

Conclusion

The main research question of this article was ‘Do compensation processes impair mental health?’. We carefully conclude that the compensation process slightly impairs mental health. The compensation process as such only slightly impaired mental health because three-quarters of the mental health complaints at post measurement was already present at baseline. We conclude carefully because the quality of evidence was very limited, mainly due to low quality study designs and heterogeneity caused by different compensation systems and various measurement points. We hope more large prospective cohort studies with standardised time points and thoroughly described compensation systems will be conducted in the future to be able to draw more solid conclusions about the effect of compensation on health.

Conflict of interest

All authors declare that they do not have any conflict of interest.

Acknowledgments

We thank Rene Otten, medical information specialist (VU Medical Centre), for his contribution in developing the search strategy. We would also like to thank Filip Smit, professor Evidence-Based Public Mental Health (VU University Medical Centre) and Riekie de Vet, professor in Clinimetrics (VU University Medical Centre), for their help in interpreting the NOS quality assessment tool.

Funding: The study was funded by the Faculty of Law, VU University Amsterdam.
