Background: Non-specific chest symptoms associated with coronary artery spasm (CAS) remain underdiagnosed and consequently undertreated. Our center applies a policy of systematic CAS detection by provocative tests (PT) in normal or near normal coronary arteries in patients with symptoms compatible with vasospastic origin. We retrospectively studied the prevalence of CAS, safety of PTs and patient outcome over a 10-year period.

Methods: From December 2002 to July 2012, 13,902 patients underwent 18,454 coronary angiographies. 5,962 of these patients with normal or near normal arteries underwent 2,397 PTs. 256 were consequentially diagnosed with CAS (10.7%). In addition, among the 7,940 patients with a ≥50% stenosis on coronary angiography, 44 patients were diagnosed as having a spontaneous CAS (0.6%).

Results: Compared to the overall population, patients with CAS were more often female (44.7% vs. <0.0001), younger (55 [47.5-64] years vs. 61 [52-70] years; p=0.0001), and more often smokers (63.7% vs. 42.3%; p<0.0001). Initial presentation was more frequently acute coronary syndrome (37.4% vs. 28.9%) and non-specific chest pain (41.8% vs. 21.6%). Sixty-nine patients had refractory CAS when PT was abnormal under antispastic treatment. 99.1% of the patients who underwent a PT had an event-free hospital course. At 46 months, the all-cause death (1.2 years, TVF occurred in 11 deferred lesions (7.2%). The significant difference in post-stent FFR between lesions with or without TLR (0.89±0.07 vs. 0.89±0.07; p=0.86). After grading lesions to 5 categories according to the post-stent FFR (0.75 to 0.80, 0.81 to 0.85, 0.86 to 0.90, 0.91 to 0.95, and 0.96 to 1.00), there was no significant difference in the incidence of TLR among 5 categories (18.8%, 3.1%, 4.4%, 8.8%, 10.3%; p=0.32). Conclusion: In patients who were treated with DES, post-stent FFR is not a predictor of long-term adverse event.

Deferred Coronary Lesion With A Gray Zone Fractional Flow Reserve In Patients With Intermediate Stenosis Is At Higher Risk Of Future Coronary Events

Background: Previous studies have identified post-stent fractional flow reserve (FFR) >0.90 as a useful surrogate for favorable long-term clinical outcome after bare-metal stent implantation. However, the prognostic value of post-stent FFR after drug-eluting stent (DES) implantation remains undetermined.

Methods: For 156 DES implanted lesions, FFR measurement at maximum hyperemia was performed after stent implantation. Follow-up angiography was scheduled between 6 and 12 months after index intervention. Angiography was also performed in the late phase based on patient’s clinical conditions and physician’s decision. The relationship between post-FFR and target lesion revascularization (TLR) was evaluated.

Results: A FFR value was significantly increased by stent implantation from 0.69±0.12 to 0.88±0.06 (p<0.0001). A FFR value > 0.90 was achieved in 63 patients (40.3%). During follow-up, TLR occurred in 12 lesions (7.7%). There was no significant difference in post-stent FFR between lesions with or without TLR (0.89±0.07 vs. 0.89±0.07; p=0.86). After grading lesions to 5 categories according to the post-stent FFR (0.75 to 0.80, 0.81 to 0.85, 0.86 to 0.90, 0.91 to 0.95, and 0.96 to 1.00), there was no significant difference in the incidence of TLR among 5 categories (18.8%, 3.1%, 4.4%, 8.8%, 10.3%; p=0.32). Conclusion: In patients who were treated with DES, post-stent FFR is not a predictor of long-term adverse event.

Endothelial function and STEMI vessel patency

Background: STEMI patients who present with open culprit vessels have on average better clinical outcome. Functional endothelium regulates platelet aggregation, controls endogenous fibrinolysis, and may play a crucial role for culprit vessel patency in the setting of STEMI. Nevertheless, clinical data on the relation between endothelial function and culprit vessel patency in STEMI patients are scarce.

Methods: This prospective cohort study included 61 STEMI patients, who had all undergone primary percutaneous coronary intervention (PCI). Four to six weeks later, endothelial function was non-invasively assessed by use of the reactive hyperemia peripheral artery tonometry (RH-PAT) method. Results: The RH-PAT index measured on average 1.89±0.57. In patients with patent culprit vessels before PCI (n=26, 42.6%), endothelial function was significantly better than in patients with occluded culprit vessels (n=35, 57.4%) (RH-PAT index 2.09±0.62 vs. 1.74±0.48; p<0.01). Compared to patients with normal endothelial function, the quintile of patients with the most severe endothelial dysfunction had a nine-fold higher risk of presenting with an occluded culprit vessel (OR 9.0, 95% CI 1.4-58.4). Logistic regression analysis revealed that this relation between endothelial function and vessel patency became even stronger after adjustment for potential confounders (adjusted OR 13.3, 95% CI 1.3-134.0).
