Virulence genes

Prevalence

ABSTRACT

Objectives: To evaluate the prevalence of some virulence genes among 510 clinical *Enterococcus* spp. isolates and to assess the association of those genes with the species, infection site, and patient group (inpatients/outpatients).

Methods: Adhesins genes (aggregation substances *agg* and *asa1* of *Enterococcus faecalis* and *Enterococcus faecium*, respectively), enterococcal surface protein (*esp*), endocarditis-specific antigen A (*efaA*), collagen-binding proteins (*ace/acm*); invasins (*hyaluronidase (hyl)* and *gelatinase (gelE)*); cytotoxines (activation of *cytolysin (cylA)* in *E. faecalis*); and modulators of the host immunity and inflammation (enhanced expression pheromone (*eep*) in *E. faecalis*) were detected by polymerase chain reaction.

Results: The overall prevalence was: *esp* – 44.3%, *agg/asa1* – 38.4%, *ace/acm* – 64.3%, *efaA* – 85.9%, *eep* – 69.4%, *gelE* – 64.3%, *hyl* – 25.1%, and *cylA* – 47.1%. *E. faecalis* isolates had significantly higher frequency of adhesin genes (*esp* and *agg/asa1*) and gelatinase in comparison to *E. faecium*. Multiple virulence genes in *E. faecalis* were significantly more prevalent than in *E. faecium* isolates. Domination of *E. faecium* with or without only one gene compared to the isolates of *E. faecalis* were found. *Enterococcus* spp. isolates obtained from outpatients compared to inpatients isolates had significantly higher frequency of *agg/asa1*, *eep*, *gelE* and *cylA*. Some adhesins genes (*esp*, *agg/asa1* and *efaA*) had higher prevalence among the non-invasive *Enterococcus* spp. isolates compared to those causing invasive bacteraemia, while *ace/acm* revealed higher dissemination in isolates causing invasive infections compared to non-invasive isolates.

Conclusion: Most *E. faecalis* attaches to abiotic surfaces in hospital environment, which correlates with higher prevalence of gene encoding for virulence factors involved in biofilm

formation, such as enterococcal surface protein, aggregation substance, and gelatinase. The intestinal tract is an important reservoir for opportunistic enterococcal pathogens and allows them to access infectious sites through different virulence factors, demonstrated in outpatient isolates in this study.

Introduction

Enterococci (mostly *Enterococcus faecalis* and *Enterococcus faecium*) are natural inhabitants of the gastrointestinal tract of humans and animals,¹ but are also found in other anatomical sites, including the vagina and oral cavity,² and in the soil, water, plants, and food.³⁻⁵ Several reports have documented that the two most important species are among the leading causes of opportunistic human infections,⁶ including urinary tract infections,⁷ infections of the surgical site and burn wound infections,^{8,9} bacteraemia and sepsis,¹⁰ endocarditis,¹¹ cholecystitis,¹² peritonitis,¹³ neonatal meningitis,¹⁴ and others.

The severe infections caused by *Enterococcus* spp. are difficult to treat due to the organism's capacity to survive in the hospital environment, their intrinsic resistance to many antimicrobials, their remarkable ability to acquire further resistance mechanisms toward strategic antibiotics during the treatment period and a variety of virulence factors.¹⁵

Virulence factors contribute to the pathogenesis of enterococcal infections through mediation of adhesion, colonization and invasion into the host tissues, modulation of the host immunity, and extracellular production of enzymes and toxins, which enhance the severity of the infection.¹⁶ Many virulence factors, such as the enterococcal surface protein (Esp), aggregation substance, capsule formation and gelatinase, are involved in bacterial adherence to host cells and/or in biofilm formation on abiotic surfaces in hospital environment.¹⁷⁻²¹ Biofilm production has an important role in the pathogenesis of enterococcal infections and also favors disease sustenance because of restricted penetration of antimicrobials.¹⁹ Invasion is usually facilitated by damage to host tissues and presence of virulence factors, including hyaluronidase and gelatinase, which assist in the advancement and further survival in newly infected places.²¹

Currently, our knowledge about the possible relationship between the presence of virulence factors and their implication in human enterococcal infections is still limited.

The aim of the present study was to examine the prevalence of genes encoding cell-associated and extracellular virulence factors in clinically relevant isolates of *Enterococcus* spp. and to assess the association of those genes with species, infection site, and patient population (inpatients or outpatients).

Materials and methods

Bacterial isolates

A collection of 510 non-duplicate clinical strains of *Enterococcus* spp., causing symptomatic infections, was investigated. All

urinary tract infections were associated with significant bacteruria ($\geq 10^5$ CFU/mL). The isolates were recovered between June 2013 and June 2015 from 398 inpatients and 112 outpatients in seven large Bulgarian hospitals. They were obtained from urine ($n = 256$), surgical wound or abscesses ($n = 138$), genital tract samples ($n = 74$), blood ($n = 26$), peritoneal fluid ($n = 6$), lower respiratory tract samples ($n = 8$), and bile ($n = 2$). *E. faecalis* ATCC 29212 and *E. faecium* ATCC 19434 were used as control strains for species identification with biochemical and molecular genetic techniques.

Culture media

HiCrome *E. faecium* Agar Base (Himedia Labs) was applied to isolate *Enterococcus* spp. strains. *E. faecalis* forms blue colonies, while *E. faecium* gives green colonies, surrounded by yellowish coloring of the ambient.

Biochemical identification with commercial kits and systems

Species identification was done using API Rapid ID 32 Strep (bioMérieux), BBL Crystal Gram-positive ID kit (Becton Dickinson) and the automated system VITEK 2 (bioMérieux).

DNA isolation

Total DNA from all used strains was extracted with GenEluteTM Bacterial Genomic DNA Kit (Sigma-Aldrich), according to the manufacturer's instructions, from 3 mL overnight cultures inoculated with a single colony.

Molecular genetic genus and species identification

Polymerase chain reaction (PCR) amplification of the 16S rRNA gene of *Enterococcus* spp. was used for genus identification of all isolates included in this study. The *sodA* genes encoding the enzyme manganese-dependent superoxide dismutase in the most common enterococci (*E. faecalis*, *E. faecium* and *Enterococcus durans*) were detected with multiplex PCR. *E. faecalis* identification was confirmed by PCR for the *eda1* gene (encoding 2-keto-3-deoxy-6-phosphogluconate aldolase, which is an enzyme involved in the Entner-Doudoroff pathway and is species-specific for *E. faecalis*). Oligonucleotides used as primers and amplification conditions were previously described.²²

PCR assay for detection of virulence genes

PCR amplification was performed in order to confirm the presence of genes coding for different virulence factors: adhesins

(aggregation substance – *agg* and *asa1* of *E. faecalis* and *E. faecium*, respectively), enterococcal surface protein (*esp* for both species), endocarditis-specific antigen A (*efA*A for both species), collagen-binding proteins (*ace/acm*); invasins (extracellular metalloendopeptidase also called gelatinase – *gelE* for both species, hyaluronidase – *hyl* for both species); cytotoxines (activation of cytolysin (class I bacteriocin) – *cylA* in *E. faecalis*) and modulators of the host immunity and inflammation (sex pheromones – enhanced expression pheromone, *eep* in *E. faecalis*). Oligonucleotides used for specific amplification primers (Alpha DNA) were previously published in the literature^{23–29} and are shown in eTable 1 (see the E-supplemental material).

Supplementary Table 1 related to this article can be found, in the online version, at <http://dx.doi.org/10.1016/j.bjid.2015.11.011>.

PCR was carried out with 2 µL template DNA, 0.25 µM of each primer, 0.2 mM deoxyribonucleoside triphosphates, 1× reaction buffer, 2 mM MgCl₂ and 0.5 U Prime Taq DNA polymerase (Genet Bio) in a total volume of 25 µL. The DNA was amplified in Gene Pro Thermal Cycler (Bioer) using the following protocol: initial denaturation (94°C for 5 min), followed by 25–30 cycles of denaturation (94°C for 35–45 s), annealing (50–68°C, from 45 s to 1 min) and extension (72°C, from 45 s to 1 min 35 s), with a single final extension of 7 min at 72°C. PCR products were separated in 1% agarose gel for 50–110 min at 130 V, stained with ethidium bromide (0.5 µg/mL) and detected by UV transillumination (wavelength 312 nm). Amplified genes were identified on the basis of fragment size presented in eTable 1.

Statistical analysis

The distribution of virulence genes with respect to both species and isolate origin was compared using Student's t-test. For a simple comparison tests a *p*-value below 0.05 was considered statistically significant. In order to counteract the problem of multiple comparisons, when they were used, a Bonferroni correction with a critical value of *p*=0.00625 was applied.

Results

Prevalence of virulence genes among all studied Enterococcus spp. isolates (n=510)

The established overall frequencies of the studied genes encoding adhesins (*esp*, *agg/asa1*, *ace/acm*, *efA*A),

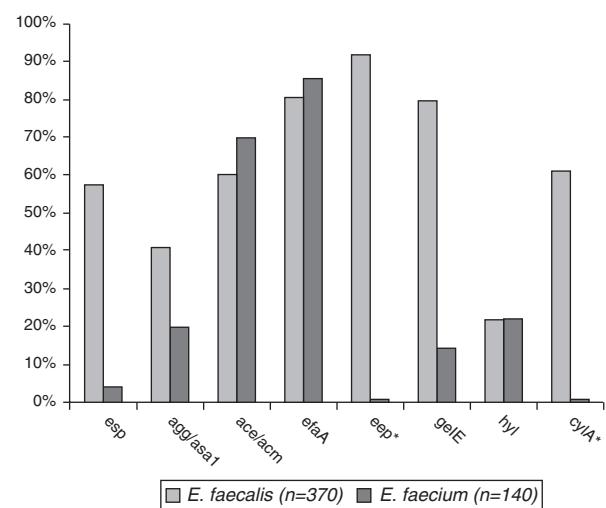

Fig. 1 – Comparative frequency of virulence genes in *E. faecalis* and *E. faecium* isolates. *Genes found only in *E. faecalis*.

modulators of the host immunity and inflammation (*eep*), invasins (*gelE*, *hyl*), and cytotoxins (*cylA*) were as follows: 44.3%, 38.4%, 64.3%, 85.9%, 69.4%, 64.3%, 25.1%, and 47.1%.

Comparative prevalence of virulence genes among *E. faecalis* (n=370) and *E. faecium* (n=110)

The prevalence of virulence genes in the two species was *esp* – 59.5% in *E. faecalis* and 4.3% in *E. faecium* (*p*<0.001), *agg/asa1* – 44.3% vs. 22.8% (*p*<0.001), *ace/acm* – 61.1%/72.8%, *efA*A – 84.9%/88.5%, *gelE* – 82.2%/17.1% (*p*<0.001), and *hyl* – 25.3%/24.2%. *eep* was found in 95.7% of *E. faecalis* isolates and *cylA* in 64.9% (Fig. 1).

The genes associated with virulence potential of the studied *E. faecalis* and *E. faecium* isolates are shown in Tables 1A and 1B. It should be pointed out in these tables the significantly higher prevalence of *E. faecalis* with multiple virulence determinants (over 4) compared to *E. faecium* (71.9% vs. 1.5%, *p*<0.001), whereas isolates with only one determinant significantly prevailed in *E. faecium* compared to *E. faecalis* (50.0%/1.1%, *p*<0.001).

Comparative prevalence of virulence genes in Enterococcus spp. with respect to the infection site

Table 2 lists the prevalence of virulence genes of all enterococci isolates, as well as the prevalence in each enterococcal species, broken down by the infection site. The following are the most important results found:

- The genes for some adhesins (*esp*; *agg/asa1* and *efA*) were significantly more prevalent among the non-invasive isolates of *Enterococcus* spp. (51.4% in genital tract infection (GTI) isolates, 39.1–59.5% in wound and GTI isolates, and 93.8% in urinary tract infection (UTI) isolates) compared to the invasive bacteremia isolates (respectively, 23.1%, 15.4%, and 61.5%) ($p < 0.001$ –0.05), while *ace/acm* revealed a significantly higher frequency ($p < 0.02$ –0.05) in invasive isolates (84.6%) compared to the non-invasive GTI and wound isolates (54.1% and 59.4%, respectively).
- For *E. faecalis*, *agg* was more frequent in isolates from the genital tract (57.1%) in comparison to the isolates from blood (22.2%) – $p < 0.05$, while *efA* was more common in isolates from UTI (94.3%) vs. from wound samples (72.9%) – $p < 0.01$.
- For *E. faecium*, there were no significant differences in the distributions of genes encoding virulence factors, according to the infection site, but isolates from blood stream infections (n = 8) were not considered due to their low number.

Comparative prevalence of virulence genes among Enterococcus spp. isolates obtained from inpatients (n = 398) and outpatients (n = 112) with symptomatic infections

Enterococcus spp. isolates from outpatients had significantly higher prevalence ($p < 0.001$ –0.02) of the following virulence genes compared to the isolates from inpatients: *agg/asa1* (58.9%/32.7%), *eep* (92.9%/62.8%), *gelE* (78.6%/60.3%), and *cylA* (73.2%/37.9%) – Fig. 2.

Discussion

In this study, we found a significantly higher prevalence ($p < 0.001$) of genes encoding some virulence factors involved in biofilm formation (the enterococcal surface protein (*esp*), aggregation substance (*agg*) and gelatinase (*gelE*)) in *E. faecalis*, compared to *E. faecium*. A previous study indicated higher prevalence of biofilm formation among *E. faecalis* strains

compared to other enterococcal species.³⁰ *E. faecalis* has been recognized as the enterococcal species most commonly infecting indwelling medical devices.^{17,30} In a study conducted by Dupré et al. with clinically relevant enterococcal isolates from a hospital in Sardinia, Italy, in the period of 1998–2001 there was a complete absence of genes for gelatinase and aggregation substance in *E. faecium*, but contrary to our results, higher frequency of *esp* in *E. faecium* vs. *E. faecalis* was reported (71.9%/60%).²³

The prevalence of *efA*, *eep*, *gelE*, and *cylA* in *E. faecalis* isolates in our study was significantly higher than previously published data on clinical strains of *E. faecalis* from Brazil in 2004 – as it follows: 84.9%/58.9%; 95.7%/58.9%; 82.2%/45.3%; 64.9%/16.8% ($p < 0.001$), while the gene frequency for *agg* and *esp* had similar rates in both studies (44.3%/36.8%, and 59.5%/57.9%).²⁹ Detection of genes for adhesins (*esp*, *agg*, *ace* and *efA*) in newer clinical *E. faecalis* isolates from Southern Brazil was more frequent than the rates found in our study (respectively, 68.4% in Brazil vs. 59.5% in our study, 57.9%/44.3%, 73.7%/61.1% and 100%/84.9%). In contrast, genes for *gelE* and *cylA* were more frequent in our isolates than among the Brazilian isolates (77.2%/82.2% and 54.4%/64.9%, respectively).³¹ A recent study of clinical isolates of *E. faecalis* in Italy showed a significantly lower frequency of *cylA* compared to our isolates (26.4%/64.9%, $p < 0.001$), and close to our distribution of *esp*, *agg*, *ace* and *efA* (52.7%/59.5%; 42.8%/44.3%; 67%/61.1%; 96.7%/84.9%).³²

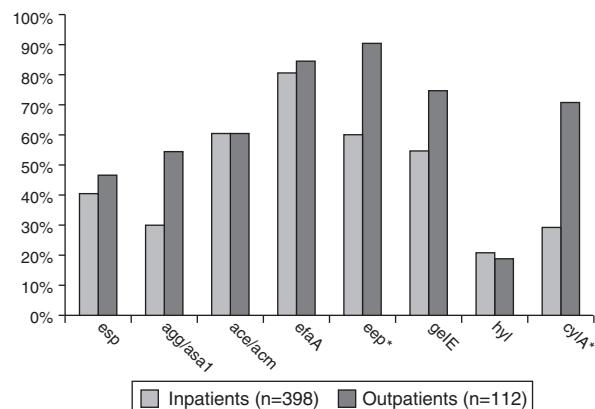

Fig. 2 – Comparative frequency of virulence genes in Enterococcus spp. isolates, causing symptomatic infections in inpatients and outpatients. *Genes found only in *E. faecalis*.

Table 2 – Prevalence of virulence genes in 510 clinical *Enterococcus* spp. (370 *E. faecalis* and 140 *E. faecium*) isolates according to the site of infection.

^a Genital tract specimens – sperm, urethral, vaginal and cervical samples.

^b others – peritoneal fluid (n = 6), bile (n = 2) and lower respiratory tract samples (n = 8).

A multicenter study on the distribution of virulence determinants in fecal *E. faecium* isolates from patients in 13 hospitals from nine European countries showed total absence of *asa1* and *gelE*, lower frequency of *hyl* in comparison to *E. faecium* isolates (17%/24.2%) of our study and significantly higher prevalence of *esp* (65% vs. 4.3%, p < 0.001).²⁶

The significantly higher prevalence of clinical *E. faecalis* isolates with multiple virulence determinants (over 4) compared to *E. faecium*, and the significant predominance of *E. faecium* isolates with one gene compared to *E. faecalis*, demonstrated in this study, was also recently found by Padmasini et al.³³ According to another study of enterococci from clinical isolates and starter cultures, all strains of *E. faecalis* were characterized by a high number of virulence genes (between 6 and 11), while the *E. faecium* strains had no such gene determinants.²⁵

In Italy, Creti et al. reported wider distribution of *esp* in non-invasive *E. faecalis* isolates (56.2%) compared to invasive isolates (38.4%).²⁸ In our study *esp* was found in 33.3% of infections caused by *E. faecalis*, with bacteremia in the clinical course, while the frequency of *esp* in non-invasive infections varied from 54.3% (in GTIs) to 64.8% (in UTIs), which confirms the important role of Esp as a colonizing factor in UTIs.³⁴ The

frequency of *esp* among our UTI *E. faecalis* isolates (64.8%) was very similar to the rate reported by Creti et al. (66.7%). The findings for *cylA* in both studies were similar: 44.4% in invasive isolates from bacteremia in our data vs. 50% in the Italian study, as well as the results for *cylA* in non-invasive isolates – varying from 62.5% to 77.1% in our study and 62.5% in the Italian study.²⁸

Recently Padilla et al. published their data on incidence of virulence genes amongst strains of *E. faecalis* isolated from UTIs and bacteremia in Chile, for the period of 2008–2009.³⁵ The rates for the following genes from urine samples in our study were significantly higher than those reported in Chile: *efaa* (94.3%/62%, p < 0.001), *eep* (98.9%/72%, p < 0.001), *gelE* (83%/28%, p < 0.001), *cylA* (62.5%/40%, p < 0.01); while the presence of *agg* was significantly lower (43.2%/78%, p < 0.001). Our isolates from bacteremia showed a significantly higher frequency of *efaa* compared to the Chilean isolates (66.7%/28%, p < 0.001).

E. faecalis isolates from patients with UTIs and wound infections in the present study showed higher prevalence of numerous virulence genes, compared to similar isolates from Brazil, studied by Bittencourt de Marques and Suzart – *esp* (64.9% and 60.4% vs. 62% and 46.1%), *agg* (43.2% and 43.8%/38%

and 38.5%), *efA* (94.3% ($p < 0.001$) and 72.9%/54% and 69.2%), *eep* (98.9% ($p < 0.001$) and 93.8% ($p < 0.001$)/58% and 53.8%), *gelE* (83% ($p < 0.001$) and 81.3% ($p < 0.001$)/50% and 34.6%) and *cylA* (62.5% ($p < 0.001$) and 64.6% ($p < 0.001$)/22% and 3.8%).²⁹

An interesting finding from the present study was the higher dissemination rates of gene determinants for some virulence factors among *Enterococcus* spp. causing infections in outpatients, compared to those infecting inpatients. The review of published medical literature could not find a similar comparative study. Hospitalized patients may have a greater incidence of enterococcal infections not only because of virulence, but because the hospital itself is a risky hub. On the other hand, the intestinal tract is an important reservoir for opportunistic pathogens such as enterococci and allows them to access infected sites especially in outpatients through different virulence factors.²¹ A weakness of this comparative analysis results from the difficulties to obtain epidemiological data; often UTIs, occurring in inpatients, begin before admission to the hospital.

Conclusions

In the present study clinical *E. faecalis* isolates were characterized by a significantly higher frequency of genes encoding some adhesins and gelatinase in comparison to *E. faecium* isolates. The higher virulence potential of *E. faecalis* vs. *E. faecium* isolates was proven (on the basis of a significantly higher prevalence of *E. faecalis* isolates with multiple virulence factor genes vs. *E. faecium* and significant predominance of *E. faecium* isolates without or with only one gene compared to the *E. faecalis*).

The genes for some adhesins (*esp* and *agg/asa1*) were more prevalent in non-invasive *Enterococcus* spp. isolates than in invasive isolates from bacteremia, while *ace/acm* showed a significantly higher frequency among invasive isolates.

For the first time, we proved that *Enterococcus* spp. isolates from outpatients with symptomatic infections had significantly higher frequency of the following virulence genes: *agg/asa1*, *eep*, *gelE* and *cylA*, in comparison to isolates causing infections in inpatients.

To the best of our knowledge, this is the first study in Bulgaria and in the Balkans region of the genes associated cellular and extracellular virulence factors among clinically relevant *Enterococcus* spp. isolates, in which a comparative analysis with respect to different features (species of microorganism, infection site, and origin) was made. Our results may serve as a basis for additional research of the pathogenesis of infections caused by *Enterococcus* spp.
