REVIEW

ABO₃-based photocatalysts for water splitting

Jinwen Shi, Liejin Guo*

International Research Center for Renewable Energy, State Key Laboratory of Multiphase Flow in Power Engineering (MFPE), Xi'an Jiaotong University (XJTU), 28 West Xianning Road, Xi'an, Shaanxi 710049, China

Abstract   ABO₃-based photocatalysts for water splitting were systematically reviewed in this manuscript. Crystal structure and chemical composition characteristics of ABO₃ materials were briefly introduced to guide the modification of ABO₃-based photocatalysts. The ABO₃-based photocatalysts were then reviewed in detail and divided into four groups based on the employed modification strategies, i.e., chemical component adjustment, micro-/nano-structure adjustment, local lattice structure adjustment, and application of the modification strategy of ABO₃ photocatalysts in designing $A_xB_yO_z$ photocatalysts. In this section, the recent research works on ABO₃-based photocatalysts in our group were presented. Finally, application of ABO₃ photocatalysts in Z-scheme systems for overall water splitting was introduced. This review summarized the development of ABO₃-based photocatalysts and showed the values and possible direction of future research, thereby offering a guide for photocatalytic water splitting.

1.   Introduction

Energy shortage and environmental pollution have become two urgent problems that restrict social development and endanger human survival. In order to resolve the two issues and to realize the sustainable development of society, the most effective route is the active development and utilization of clean and renewable energy sources, among which solar energy is the most promising candidate due to its abundant reservation and wide distribution. However, the large scale utilization of solar energy is still restricted at present due to its low energy density, high geographical dispersion, high time instability, and inconvenience for storage. H₂ is a kind of superior energy carrier and ideal clean and renewable energy due to its high energy density, no pollution from the combustion products, convenience for storage and transportation. Consequently, exploring and realizing the conversion and storage of solar energy as hydrogen energy is a powerful route to develop and utilize renewable energy [1]. Photocatalytic H₂ evolution under solar light irradiation has shown good prospect for such a conversion, and photocatalytic overall water splitting to form both H₂ and O₂ stoichiometrically under solar light irradiation is the ultimate goal to realize such a conversion by

Production and hosting by Elsevier

photocatalysis [2]. Furthermore, in order to develop the system for photocatalytic overall water splitting under solar light irradiation, it is a key task to exploit photocatalysts with high stability, high efficiency, low cost for visible-light-driven H$_2$ and O$_2$ evolution.

The developed photocatalytic materials for H$_2$ and O$_2$ evolution mainly contain inorganic semiconductors [3–7], metal organic complexes [8–10], organic semiconductors [11,12], and recently reported conductors [13], in which inorganic semiconductor photocatalysts showed great promising for future applications [14–17].

2. Semiconductor photocatalysis for water splitting

The fundamental principle and processes for semiconductor-based photocatalytic water splitting have been clearly presented in many excellent review papers [14–16,18–28] and raised the basic requirement for water-splitting photocatalysts as follows to guide the exploration of such photocatalytic materials.

Considering the fundamental principle, photocatalyst should have bandgap larger than the standard Gibbs free energy change (1.23 eV) for water splitting into H$_2$ and O$_2$, and should have conduction band with potential more negative than that for water reduction and valence band with potential more positive than that for water oxidation. Furthermore, based on the processes, firstly, photocatalyst should have bandgap smaller than the energies of incident photons to ensure the excitation of photogenerated charge carriers. Visible light accounts for around 43% of the incoming solar energy, and therefore should be fully used by photocatalysts with excellent visible-light response. Secondly, photocatalyst should have good ability to promote the separation and transfer of photogenerated charge carriers and thus to restrain their recombination. Thirdly, photocatalyst should provide enough reactive sites to accelerate redox reaction and to restrain the back-reaction. In a word, in order to improve the photocatalytic reaction, photocatalyst should enhance the generation, transfer, and reaction of photogenerated charge carriers during the whole photocatalytic process.

According to the types of anions, inorganic semiconductor photocatalysts were mainly classified as S-containing, N-containing, and oxide photocatalysts. In contrast, oxide photocatalysts generally showed unparalleled stability that is the most basic and important requirement of photocatalysts for practical application, and therefore are of great research value. However, the ability of oxide photocatalysts to utilize visible light was often intrinsically restrained by the wide bandgaps, which were usually caused by the low valence bands that consisted of O 2p orbitals with a potential of around 3.0 eV versus NHE [20]. Moreover, the activities of developed visible-light-driven oxide photocatalysts were still low [3]. Accordingly, the research focus on oxide photocatalysts should be the extension of light-response ranges and the enhancement of visible-light-driven photocatalytic activities [29].

In this review paper, we focus on ABO$_3$-based photocatalysts in view of the following characteristics of ABO$_3$ materials.

3. Characteristics of ABO$_3$ materials

3.1. Crystal structure characteristics of ABO$_3$ materials

ABO$_3$ represents a class of typical binary metal oxides. A series of ABO$_3$ with crystal structures could be obtained by using different elements and preparation conditions. By taking the

prevalent perovskite ABO$_3$ as an example, the crystal structure characteristics were introduced as follows so as to indicate the advantages and prospects of ABO$_3$ materials for the application to photocatalytic water splitting under solar irradiation.

ABO$_3$ with ideal cubic perovskite structure (space group, Pm$\bar{3}$m) is shown in Fig. 1. Metal cations in A and B sites are located in the 12- and 6-coordinated environments with O anions, respectively, and the radii of A-site cations are generally larger than those of B-site cations. Eight BO$_6$ octahedra with shared corners formed the three-dimensional framework of cubic cell, the center of which is occupied by A-site cation. The radii of cations varied due to different types and valence states of cations. Consequently, compared with the ideal cubic perovskite ABO$_3$, the real perovskite ABO$_3$ exhibited lattice distortion to varying degrees, thereby resulting in the transformation of crystal phases in the following sequences: orthogonal, rhombohedral, tetragonal, monoclinic, and triclinic phase. As far as photocatalysis is concerned, lattice distortion has important impact on crystal field and thus changes the dipole and electronic band structures, thereby influencing the behaviors of photogenerated charge carriers, including excitation, transfer, and redox reaction, in whole photocatalytic process [30–32].

3.2. Chemical composition characteristics of ABO$_3$ materials

Most metal elements in periodic table are known to be stably located in ABO$_3$ structures, and multicomponent ABO$_3$ materials can be easily synthesized by partial substitution of cations in A and B sites. In terms of photocatalysts, control of electronic band structures by adjusting elemental compositions was accepted as the effective method to extend light-response range. For this reason, ABO$_3$ structures provide the basic framework and extensive space for the combination of elemental compositions and the construction of electronic band structures in photocatalysts [33–38].

Moreover, owing to the requirement of charge balance for in A and B sites, the mixed oxidation states or unusual

Fig. 1 Ideal cubic perovskite structure for ABO$_3$ (cyan, BO$_6$ units; yellow, A atoms). Reprinted with permission from Ref. [27].

oxidation states of metal cations were expected to be maintained in ABO_3 structures. With regard to photocatalysts, valence states of elements generally play key roles in determining the ability of light response and the lifetime of photo-generated charge carriers. Accordingly, ABO_3 structures can be employed to guarantee the valence-state control of metal cations in photocatalysts [39,40].

Besides, the easy preparation and controllable physico-chemical properties make ABO_3 materials excellent model photocatalysts for the investigation of structure–activity relationships during photocatalytic reaction.

4. Development of ABO_3 photocatalysts

Based on the crystal structure and chemical component characteristics, different modification strategies (such as chemical component adjustment, micro-/nano-structure adjustment, and local lattice structure adjustment) were employed to develop ABO_3 photocatalysts with improved performance for water splitting (see Table 1).

4.1. Chemical component adjustment

The approaches to chemical component adjustment of ABO_3 photocatalysts are mainly divided into ion doping, ion replacement, multi-component solid solution, multi-component composite.

4.1.1. Ion doping
Ion doping includes interstitial doping and lattice substitution. Ions are generally doped into ABO_3 materials by means of lattice substitution. ABO_3 (such as $SrTiO_3$ [81,122–128] and $NaTaO_3$ [50]) showed unparalleled stability and high activity for photocatalytic H_2 and/or O_2 evolution especially for overall water splitting under ultraviolet (UV) irradiation [50,81,122–128], but the ability to utilize visible light was often intrinsically restrained by wide bandgaps [20]. Accordingly, metal cations were usually doped into ABO_3 (such as $SrTiO_3$ [39,49,55,56,58,73,102] and $NaTaO_3$ [120]) to tailor the electronic structures and thus to extend the light response range [20].

Konta et al. found that Ru-, Rh-, and Ir-doped $SrTiO_3$ possessed intense absorption bands in the visible light region due to excitation from the discontinuous levels formed by the dopants to the conduction band of the $SrTiO_3$ host. Mn- and Ru-doped $SrTiO_3$ showed photocatalytic activities for O_2 evolution from an aqueous silver nitrate solution while Ru-, Rh-, and Ir-doped $SrTiO_3$ loaded with Pt cocatalysts produced H_2 from an aqueous methanol solution under visible light irradiation. Pt/Rh-doped $SrTiO_3$ photocatalyst gave an AQY of 5.2% at 420 nm for the H_2 evolution reaction, and the reducible Rh species contributed to the formation of visible light absorption band and the surface reaction sites [55]. Bae et al. investigated noble metal (Ru, Rh, Ir, Pt, and Pd)-doped $SrTiO_3$ as well, and ascribed the photocatalytic activity of Pt/Rh-doped $SrTiO_3$ to its suitable band energetics, and the induced hybridized Ti/Rh orbitals in the bandgap of $SrTiO_3$ [73]. Chen et al. developed copper doped ABO_3 ($CaTiO_3$ [90] and $LaNiO_3$ [91,94]) photocatalysts for visible-light-driven H_2 evolution and attributed the enhancement of photocatalytic activity to the smaller bandgap and the lowered probability for recombination of electron–hole pairs.

Furthermore, in order to control the valence states of doped metal cations and to reduce the lattice defects in ABO_3 photocatalysts, the strategy of codoping was generally adopted to maintain the charge balance. Kudo et al. developed a series of codoped $SrTiO_3$ photocatalysts, such as (Cr,Sb)-codoped $SrTiO_3$ [49], (Cr,Ta)-codoped $SrTiO_3$ [56], and (Ni,Ta)-codoped $SrTiO_3$ [58], and applied to visible-light-driven photocatalytic H_2 evolution in methanol solution. (Cr,Sb)-codoped $SrTiO_3$ showed intense absorption bands in the visible light region and possessed 2.4 eV of energy gaps, respectively. The charge balance was kept by codoping of Sb^{5+} and Cr^{3+} ions, resulting in the suppression of formation of Cr^{6+} ions and oxygen defects in the lattice which should work as effectively nonradiative recombination centers between photogenerated electrons and holes [49]. Compared with Cr-doped $SrTiO_3$, (Cr,Ta)-codoped $SrTiO_3$ had a shorter induction period and showed higher photocatalytic activity. Codoping of tantalum ions suppressed the formation of Cr^{6+} ions and oxygen defects which would work as nonradiative recombination centers between photogenerated electrons and holes, resulting in the shortening of induction periods and the improvement of photocatalytic activities [56]. As for (Ni,Ta)-codoped $SrTiO_3$, the visible-light responses were due to the charge-transfer transition from the electron donor levels formed by the 3d orbitals of doped Ni^{2+} to the conduction bands of the host materials. (Ni,Ta)-codoped $SrTiO_3$ showed higher activity than $SrTiO_3$ doped with only nickel, because codoped Ta^{5+} ions suppressed the formation of Ni^{3+} ions that are expected to trap photogenerated electrons [58].

In addition, ion doping could be employed not only to extend the light response but also to enhance the photocatalytic activity. Ishihara et al. found for the first time that controlling the charge density in oxide semiconductors with an acceptor was effective for improving the activity for overall water splitting. Although the photodecomposition activity of $NiO/KTaO_3$ was negligible, doping small amount of acceptor (Zr^{4+}) to form NiO/Zr-doped $KTaO_3$ increased the formation rate of H_2 and O_2 [42]. Furthermore, Takata et al. examined the doping of aliovalent metal cations to $SrTiO_3$ photocatalyst for overall water splitting. It was found that doping of a cation (Na^+) with valence lower than that of the parent cation (Sr^{2+}) effectively enhanced photocatalytic activity but the doping of a cation (Ta^{5+}) with valence higher than that of the parent cation (Ti^{4+}) suppressed photocatalytic activity, because the doping of a lower valence cation introduced oxygen vacancies and decreased Ti^{3+}. The concept of defect engineering by aliovalent doping provides an example of the design of active photocatalysts [81].

Based on the above results, it could be found that both the types and valence states of doped transition metals play important roles in enabling the visible-light response and improving the photocatalytic activities, and ABO_3 hosts provide excellent platforms for the modification of ion doping. The basic requirement of charge balance in ABO_3 hosts could be flexibly utilized to intentionally control the valence states of doped transition metals and the lattice defects, thereby optimizing the photocatalytic reaction.

4.1.2. Ion replacement
Kato et al. developed $AgMO_3$ (M = Ta and Nb) photocatalysts by replacing Na^+ in $NaMO_3$ (M = Ta and Nb) with Ag^+.

Table 1 ABO$_3$-based photocatalysts for water splitting.

Photocatalyst (mass)	Preparation strategy	Lamp (filter)[a]	Reactant solution[b]	Activity/ μmol h^{-1} g$_{cat}^{-1}$[c]		AQY/% (wavelength/nm)[d]	Reference (year)
				Cocatalyst/H$_2$	Cocatalyst/O$_2$		
Ga$_{2-x}$In$_x$O$_3$	Solid-state reaction	450 W Hg	5.4 vol% CH$_3$OH/0.05 M AgNO$_3$	1 wt% Pt/30[f]	—/25[f]	–	[41] (1998)

[a] The lamp (with filter if necessary) was used as light source.
[b] Aqueous solution unless otherwise specified.
[c] g$_{cat}^{-1}$ represented "per gram photocatalyst", and mg$_{cat}^{-1}$ represented "per milligram photocatalyst".
[d] AQY represented "apparent quantum yield".
[e] The photocatalyst was used for overall water splitting.
[f] The rate unit of gas evolution was μmol h^{-1}.
[g] 200 W Hg-Xe lamp was used.

The band gaps of AgTaO$_3$ and AgNbO$_3$ were 3.4 and 2.8 eV, respectively, being 0.6 eV smaller than the band gaps of NaTaO$_3$ and NaNbO$_3$, both of which only had UV-light response. It was found that a hybrid orbital of Ag 4d and O 2p formed a valence band at a more negative level than O 2p orbitals. AgNbO$_3$ has arisen as a new visible-light-driven photocatalyst possessing the ability to evolve H$_2$ or O$_2$ from water in the presence of sacrificial reagents [48].

Sato et al. reported the ability of NaSbO$_3$ photocatalyst for overall water splitting. However, this material was only active under UV-light irradiation due to the wide bandgaps (about 4.4 eV) [44,45]. Based on the electronic configuration of Ag$^+$, Kako et al. prepared AgSbO$_3$ photocatalyst with an absorption edge up to about 480 nm and successfully applied for visible-light-driven O$_2$ evolution from an aqueous silver nitrate solution [77]. Band-structure calculation revealed that the conduction-band minimum (CBM) and valence-band maximum (VBM) of NaSbO$_3$ were composed of Sb 5s and O 2p orbitals, respectively [44,129], whereas for AgSbO$_3$, the CBM consisted of the hybridized Ag 4d and O 2p orbitals, and VBM mainly consisted of the Ag 5s and the Sb 5s orbitals. Consequently, The Ag$^+$ largely contributed to the bandgap narrowing by lifting up the valance band.

Ion replacement was proved as an effective method to construct new energy bands in ABO$_3$ photocatalysts and thus to extend the light response range.

4.1.3. Multi-component solid solution

Designing solid solutions between end-member materials with analogous crystal structures but different electronic band structures has greatly promoted the development of photocatalysts in recent years [4,41]. On account of the highly susceptible substitution of different cations at both A and B sites of ABO$_3$-type perovskite oxides [39,130], the derived solid solutions with versatile properties are noteworthy [34–36,38,83,106].

Due to the excellent photocatalytic performance of SrTiO$_3$ and NaTaO$_3$ for overall water splitting under UV irradiation [50,123] and the inability of the two materials for harnessing visible light, a series of SrTiO$_3$- and NaTaO$_3$-based solid-solution photocatalysts, such as SrTiO$_3$–AgNbO$_3$ [35,36], NaTaO$_3$–LaCoO$_3$ [34], NaTaO$_3$–LaCrO$_3$ [38], and NaTaO$_3$–NaBiO$_3$ [83], were developed and successfully applied to photocatalytic H$_2$ or O$_2$ evolution under visible-light irradiation. A novel series of solid-solution semiconductors SrTiO$_3$–AgNbO$_3$ have been developed by Wang et al. as highly visible-light-active photocatalysts for efficient O$_2$ evolution. The mixed valent perovskites (AgNbO$_3$)$_{1-x}$(SrTiO$_3$)$_x$ possess a modulated energy band structure. The conduction band is composed of the hybrid (Ti 3d+Nb 4d) orbitals and the valence band is constructed by the hybrid (O 2p+Ag 4d) orbitals. The modulation of band structure (band gap energy, band edge positions, etc.) depends on the extent of orbital hybridization. As a result of competition between the absorption ability to visible-light and the reductive/oxidative abilities, the highest visible-light activities for O$_2$ evolution are realized over (AgNbO$_3$)$_{0.75}$(SrTiO$_3$)$_{0.25}$. It was proved that making solid-solution oxide semiconductors with tunable electronic structures is a feasible band engineering approach for the development of highly visible-light-active photocatalysts.

Cubic perovskite $Na_{0.5}La_{0.5}TiO_3$ has too wide a bandgap to utilize visible light [131]. The analogous perovskite $LaCrO_3$ has a bandgap narrow enough to absorb visible light [132,133] but was reported to show trace amounts of H_2 evolved by visible-light-driven photocatalysis [38] since the conduction band level is relatively low and thus the driving force for reducing H_2O to H_2 is weakened. In our recent work, novel cubic perovskite structure photocatalyst of $Na_{0.5}La_{0.5}TiO_3$–$LaCrO_3$ solid-solution single-crystal nanocubes were prepared by means of facile, surfactant-free hydrothermal reactions at 180 °C for 48 h for the first time, and successfully applied to visible-light-driven photocatalytic H_2 evolution. The introduction of $LaCrO_3$ component into $Na_{0.5}La_{0.5}TiO_3$ rendered the further distortion of BO_6 octahedra in ABO_3, thus beneficial for the excitation, separation and migration of photogenerated charge carriers. The bandgap was dramatically narrowed by Cr^{3+} from 3.19 ($Na_{0.5}La_{0.5}TiO_3$, i.e., NaLaTi) to 2.25 eV (($Na_{0.5}La_{0.5}TiO_3$)$_{1.00}$($LaCrO_3$)$_{0.08}$, i.e., NaLaTi–0.08Cr), thereby enabling the utilization of visible light (<550 nm). The narrowing of the bandgap was reasonably explained by the band-structure calculations (see Fig. 2). The new CBM was composed of Cr 3d eg orbitals and Ti 3d orbitals, and the new VBM was formed by Cr 3d t2g orbitals rather than O 2p orbitals (see Fig. 3). The solid-solution configuration maintained the charge balance to preserve the valence of Cr^{3+} rather than Cr^{6+}, and accommodated Cr^{3+} with high content to form new energy bands instead of localized impurity levels. The hydrothermal preparation strategy ensured the formation of single crystals with high purity, few defects, and regulated morphology; it also guaranteed the valences of Ti^{4+} and Cr^{3+} in the solid solution. Consequently, owing to the solid-solution configuration and hydrothermal preparation strategy, the recombination of photogenerated carriers could be effectively suppressed to benefit photocatalytic H_2 evolution. ($Na_{0.5}La_{0.5}TiO_3$)$_{1.00}$($LaCrO_3$)$_{0.08}$ solid-solution single-crystal nanocubes showed stable visible-light-driven photocatalytic activity for H_2 evolution (rate, 8.2 µmol h^{-1} g$_{cat}^{-1}$) in methanol aqueous solution (see Fig. 4) [101].

In addition to solid solutions between two ABO_3 end-member materials, solid solutions between end-member materials of one ABO_3 and one ABX_3 perovskite oxynitride, such as $SrTiO_3$–$LaTiO_2N$ [76], $BaZrO_3$–$BaTaO_2N$ [99], and $CaZrO_3$–$CaTaO_2N$ [116], were also designed by different research groups, aiming to lift up valence band and thus to narrow the bandgaps of ABO_3 materials by incorporating N to take part in the formation of valence band. $SrTiO_3$–$LaTiO_2N$ showed photocatalytic activities for H_2 and O_2 evolution in corresponding sacrificial reagents under visible light irradiation. The band gaps of ($SrTiO_3$)$_{1-x}$($LaTiO_2N$)$_x$ reduced from 3.18 to 2.04 eV with increasing x from 0 to 0.30. Moreover, the calculated results suggested that the band gap narrowing came from the hybridization of N 2p and O 2p orbital. Matoba et al. reported a solid solution between $BaTaO_2N$ and $BaZrO_3$. Compared with that of $BaTaO_2N$, the photocatalytic activity of $BaZrO_3$–$BaTaO_2N$ was

Fig. 3 Schematic band structures of $LaCrO_3$, $Na_{0.5}La_{0.5}TiO_3$–$LaCrO_3$ solid solution, and $Na_{0.5}La_{0.5}TiO_3$. Reprinted with permission from Ref. [101].

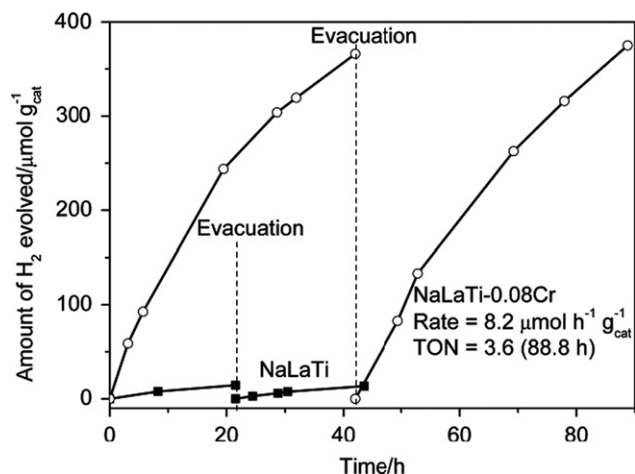

Fig. 4 Time courses of visible-light-driven H_2 evolution on photocatalysts of as-prepared NaLaTi (solid squares) and NaLaTi–0.08Cr (open circles). Reprinted with permission from Ref. [101].

improved six- to nine-fold for H_2 evolution in aqueous NaI solution under visible-light irradiation due to an increased driving force for surface redox reactions and fewer defects [99]. The analogous solid solution of $CaZrO_3$–$CaTaO_2N$ was prepared almost at the same time, and exhibit photocatalytic activity for H_2 evolution from formic acid aqueous solution under visible-light irradiation. The narrow band gap, sufficient crystallization, enough pore volume and large specific surface area resulted in the best photocatalytic activity of $(CaZrO_3)_{0.2}(CaTaO_2N)_{0.8}$ [116].

Consequently, the solid-solution construction was demonstrated to be a powerful strategy to design ABO_3-based photocatalysts, and exhibited the following merits. The band structures of photocatalysts could be optimized to mediate the competition between the absorption ability to visible-light and the reductive/oxidative abilities. The unfavorable valence states of multivalent metal cations and the lattice defects could be depressed to reduce the recombination of photogenerated charge carriers.

4.1.4. Multi-component composites

Synergistic effect on photocatalytic performance could be achieved when different materials were combined to form multi-component composites [19,25,134,135]. The ABO_3-based multi-component composites mainly include metal–ABO_3 composites [103,110,136], semiconductor–ABO_3 composites [61,87,96,97,108,121] and dye–ABO_3 composites [59,60,92]. The other components couple with ABO_3 generally functioned as cocatalysts or photosensitizers.

Domen et al. designed $SrTiO_3$ photocatalyst loaded with the classical NiO/Ni double-layer cocatalyst by reduction/oxidation pretreatment for overall water splitting. H_2 evolution occurs over NiO while O_2 evolution takes place over $SrTiO_3$, thus announced the separation of reactive sites for H_2 and O_2 evolution, respectively. Furthermore, the existence of metallic Ni between the interface of NiO and $SrTiO_3$ facilitated the transfer of electrons between both materials, and therefore enhanced the photocatalytic activity [136]. Moreover, Hu and Teng investigated the interaction between NiO cocatalyst with $NaTaO_3$ photocatalyst for overall water splitting under UV illumination. Activity increased

significantly with NiO loading and reached a maximum at first, and then decreased with further loading. It was found that the interdiffusion of Na^+ and Ni^{2+} cations created a solid-solution transition zone ($Na_xNi^{2+}_{1-2x}Ni^{3+}_xO$ and $Ni_xNa_{1-x}TaO_3$) on the outer sphere of $NaTaO_3$ (see Fig. 5). For less NiO contents, no NiO clusters appeared on the $NaTaO_3$ surface, and the reduction/oxidation pretreatment did not enhance photocatalytic activity. The high activity resulting from a low NiO loading suggests that the interdiffusion of cations heavily doped the p-type NiO and n-type $NaTaO_3$, reducing the depletion widths and facilitating charge transfers through the interface barrier [88]. By comparing the above results, It could be found that NiO was an excellent cocatalyst loaded on ABO_3 photocatalysts for overall water splitting, but the mechanisms for activity enhancement were different due to the different structural features, which were considerably affected by the interaction between cocatalyst and photocatalyst host. Further research on Ni/NiO cocatalyst loaded on ABO_3 photocatalysts (such as $Ni/NiO/Na_{1-x}La_xTaO_3$ [103] and $Ni/NiO/KNbO_3/CdS$ [68]) for H_2 evolution was also performed in other groups. In addition to NiO, other cocatalysts, such as metallic Ag [110], Au, Pt, Ag, Ni, Ce, and Fe [93] were also employed to collect photogenerated electrons and thus to promote photocatalytic H_2 evolution.

Heterojunctions could be formed by coupling other band structure-matched semiconductors with ABO_3 photocatalysts to accelerate the separation of photogenerated charge carriers.

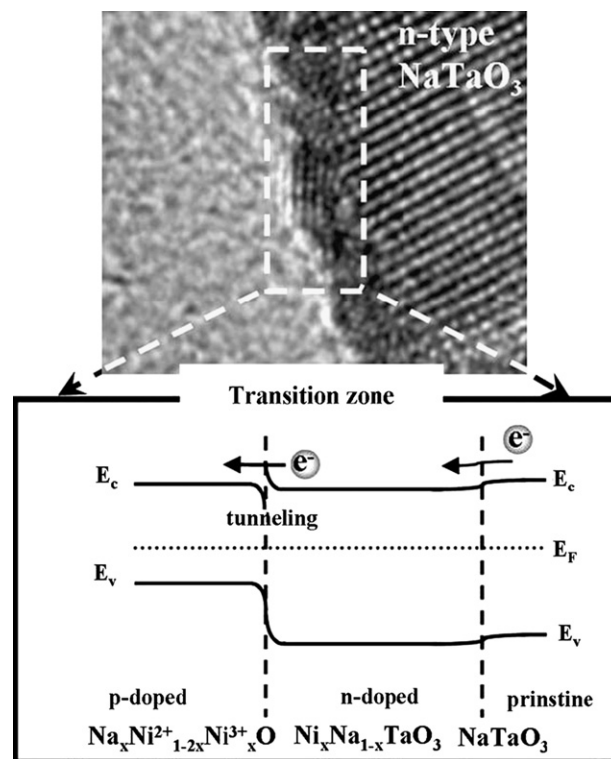

Fig. 5 Schematic energy-level diagrams of the NiO and $NaTaO_3$ contact with interdiffusion of Ni^{2+} and Na^+ to form p-doped NiO (i.e., $Na_xNi^{2+}_{1-2x}Ni^{3+}_xO$) and n-doped $NaTaO_3$ (i.e., $Ni_xNa_{1-x}TaO_3$) at the interface. Steeper band bending and reduced depletion widths appeared at the heterojunction interface. E_c, E_v, and E_F represent the energy positions of the conduction band edge, valence band edge, and Fermi level, respectively. Reprinted with permission from Ref. [88].

TiO$_2$/SrTiO$_3$ heterostructures were prepared by different groups [87,121]. Ng et al. reported that in comparison to the respective pristine semiconductor photocatalysts, the heterostructured TiO$_2$/SrTiO$_3$ film showed the highest efficiency in photocatalytic splitting of water to produce H$_2$, 4.9 times that of TiO$_2$ and 2.1 times that of SrTiO$_3$. The enhanced photocatalytic efficiency is largely attributed to the efficient separation of photogenerated charges at heterojunctions of the two dissimilar semiconductors, as well as a negative redox potential shift in the Fermi level. Furthermore, the coupled semiconductors with ABO$_3$ photocatalysts could act as photosensitizers to harness low-energy photons that could not be utilized by the ABO$_3$ host due to the wide bandgaps [61,96,97,108]. A series of SrTiO$_3$-based heterostructural photocatalysts (such as SrTiO$_3$/Fe$_2$O$_3$ SrTiO$_3$/BiFeO$_3$ [61], ZnFe$_2$O$_4$/SrTiO$_3$ [97], and C$_3$N$_4$/SrTiO$_3$ [108]) were developed and successfully applied to visible-light-driven H$_2$ evolution. Luo and Maggard reported that both SrTiO$_3$/Fe$_2$O$_3$ and SrTiO$_3$/BiFeO$_3$ systems exhibited visible-light photocatalytic activity, while pure SrTiO$_3$, Fe$_2$O$_3$, and BiFeO$_3$materials exhibit little visible-light activity. These results demonstrate that composite systems offer a unique and competitive approach to the visible-light activation of SrTiO$_3$ [61]. In addition to semiconductors, dyes (such as Eosin Y [92] and porphyrinoids [59,60]) were also employed as sensitizers to enhance the light response [92] and the separation of photogenerated charge carriers [59,60] on ABO$_3$ photocatalysts.

The above results demonstrated that constructing of ABO$_3$-based composites could not only accelerate the separation of photogenerated charge carriers by matching band structures in heterostructures, but also improve the utilization of incident light by photosensitization.

4.2. Micro-/nano-structure adjustment

Micro-/nano-structure adjustment of materials are generally achieved by employing appropriate preparation strategies [16,27,28,137–139]. As far as ABO$_3$-based photocatalysts are concerned, various preparation strategies were developed to adjust their micro-/nano-structures, aiming to optimize the photocatalytic process.

4.2.1. Solid-state reaction

Solid-state reaction is the most frequently used method to prepare ABO$_3$-based materials, but the high-temperature process generally resulted in as-prepared materials with defects and large particle sizes, which prompted the recombination of

photogenerated carriers and thus led to low activity [64]. However, researchers from Kudo' group successfully prepared NaTaO$_3$-based photocatalysts with nanostep structure by solid-state reaction [43,50,78,82]. Doping of metal cations (including lanthanides [43,50] and alkaline earth metal ions [78,82]) played the key role in constructing such a unique micro-/nano-structure. Among La, Pr, Nd, Sm, Gd, Tb and Dy, La was the most active dopant to improve the photocatalytic activity for overall water splitting under UV irradiation [43,82]. NiO/La-doped NaTaO$_3$ (i.e., NiO/NaTaO$_3$:La) showed photocatalytic activity 9 times higher than nondoped NiO/NaTaO$_3$. The maximum AQY was 56% at 270 nm, thus setting the highest record for overall water splitting under UV irradiation. It was found that the particle sizes of La-doped NaTaO$_3$ crystals were smaller than that of the nondoped NaTaO$_3$ crystal and that the ordered surface nanostructure with characteristic steps was created by the lanthanum doping. The small particle size with a high crystallinity promoted the reaction of photogenerated electrons and holes with water molecules. NiO cocatalysts were loaded on the edge of the nanostep structure of La-doped NaTaO$_3$ photocatalysts as ultrafine particles. The H$_2$ evolution proceeded on the ultrafine NiO particles loaded on the edge while the O$_2$ evolution occurred at the groove of the nanostep structure. Consequently, the reaction sites for H$_2$ evolution were separated from those of O$_2$ evolution over the ordered nanostep structure. Both the small particle size and the ordered surface nanostructure of the NiO/La-doped NaTaO$_3$ photocatalyst contributed to the highly efficient overall water splitting (see Fig. 6) [43].

4.2.2. Hydrothermal/solvothermal reaction

Hydrothermal/solvothermal synthesis was widely acknowledged as a powerful tool to generate products with high crystallinity and purity, few defects, and novel morphologies. The technological efficiency in developing bigger, purer, and dislocation-free single crystals is of much importance [140].

Chen and Ye successfully prepared dumbbell-like and rod-like SrSnO$_3$ nanostructures by a facile hydrothermal process and subsequent heat-treatment process. Compared with the sample from solid-state reaction, the as-prepared SrSnO$_3$ nanostructures showed higher activity for H$_2$ and O$_2$ evolution in corresponding sacrificial reagents under UV light irradiation due to the higher surface area and fewer defects [64]. Ding et al. synthesized KNbO$_3$ single-crystal nanowires by a hydrothermal method. The prepared nanowires achieved the highest photocatalytic activity in all reported KNbO$_3$

Fig. 6 Mechanism of highly efficient photocatalytic water splitting over NiO/NaTaO$_3$:La photocatalysts. Reprinted with permission from Ref. [50].

materials for H_2 evolution from aqueous CH_3OH solutions because of the high surface area and high crystallinity [75]. Yu et al. from the same group synthesized Cr-doped $SrTiO_3$ with high specific surface areas (19.3–65.4 $m^2 g^{-1}$), and good crystallinity, and small crystalline size (20–30 nm) by using a sol–gel hydrothermal method. The as-prepared Pt/Cr-doped $SrTiO_3$ photocatalyst exhibited H_2 evolution rate 3 times higher than that of the sample from solid-state reaction in methanol solution under visible light irradiation due to the high specific surface area and good crystallinity [102]. Joshi et al. synthesized $BiFeO_3$ single-crystal nanocubes via simple microwave-hydrothermal procedure in sizes of 50–200 nm and successfully applied to photocatalytic O_2 evolution in $FeCl_2$ solution. The microwave condition largely shortened the reaction time (only 30 min) [69]. The hydrothermal conditions have important effects on the physicochemical properties and photocatalytic performance of ABO_3 materials. Quaternary perovskite oxide $Na_{0.5}Bi_{0.5}TiO_3$ hierarchical microspheres was synthesized by Wang and Wang via a low-temperature hydrothermal route. The alkaline concentration played crucial roles in the physicochemical properties and the photocatalytic activities. $Na_{0.5}Bi_{0.5}TiO_3$ microspheres prepared with 9 M NaOH exhibited the highest rate of H_2 evolution under UV and visible light, because the highest conduction band edge and the smallest particle sizes led to the suppression of electron–hole recombination [119]. Using a three-dimensional mesoporous carbon as template to provide the confined space, Yokoi et al. prepared a colloidal array of $NaTaO_3$ nanoparticles in size of 20 nm and with a surface area of 34 $m^2 g^{-1}$ by a hydrothermal reaction. The colloidal array of $NiO/NaTaO_3$ nanoparticles showed photocatalytic activity for overall water splitting under UV irradiation more than three times as high as non-structured bulk $NaTaO_3$ particles [104].

The above results confirmed the advantages of hydrothermal/solvothermal reaction in preparing ABO_3-based photocatalysts with high crystallinity, few defects, small sizes, large surface areas, and special micro-/nano-structures.

4.2.3. Spray pyrolysis process

Spray pyrolysis process is an aerosol process to produce powders of highly uniform in morphology and composition because of short residence time and droplets of several micrometers in which precursors are distributed uniformly before evaporation and decomposition. Park et al. prepared a series of ABO_3-based photocatalysts (such as (Cr,Ta)-codoped $SrTiO_3$ [109], (Ni,M)-codoped $SrTiO_3$ (M = La or Ta) [117], and $NaBi_xTa_{1-x}O_3$ [118]) by this method. Compared with (Cr,Ta)-codoped $SrTiO_3$ photocatalyst prepared by solid-state reaction, the photocatalyst prepared by spray pyrolysis showed a higher (about 100 times) H_2 evolution rate and shorter (8 times) induction period in aqueous methanol solution under visible-light irradiation because of the increased surface roughness, compositional uniformity, and surface area, and the smaller amount of Cr^{6+} [109]. Another two photocatalysts, (Ni,La)-codoped $SrTiO_3$ and (Ni,Ta)-codoped $SrTiO_3$, were also prepared by continuous spray pyrolysis. Furthermore, solid-solution $NaBi_xTa_{1-x}O_3$ photocatalysts were prepared by spray pyrolysis process. Compared with that of photocatalyst prepared by the hydrothermal method, the H_2 evolution rate of $NaBi_xTa_{1-x}O_3$

photocatalysts from spray pyrolysis was enhanced almost 20 times in aqueous methanol solution under visible-light irradiation, because of the compositional uniformity and unique surface morphology with large BET surface area of the photocatalyst. The composition of the photocatalyst was optimized at $NaBi_{0.07}Ta_{0.93}O_3$.

4.2.4. Multi-step reaction

In our group, aiming to enhance the visible-light-driven photocatalytic activity, ABO_3 with novel micro-/nano-structures were designed and prepared, and successfully applied to visible-light-driven photocatalytic H_2 or O_2 evolution [112,114]. Hexagonal single-crystal nanosheet-based $NaSbO_3$ hierarchical cuboidal microclusters (i.e., HCMCs) with exposed {001} facets were prepared by means of a facile, surfactant-free hydrothermal reaction at 250 °C for 48 h for the first time. Their growth mechanism was investigated by systematically examining the effect of hydrothermal treatment time and temperature on the crystal structures and particle morphologies of products. Furthermore, based on the similar crystal structure (rhombohedral-phase ilmenite) between $NaSbO_3$ and $AgSbO_3$ to facilitate topotactic transformation, hexagonal single-crystal nanosheet-based $AgSbO_3$ hierarchical cuboidal microclusters with exposed {001} facets were prepared by performing an ion exchange of Ag^+ on the sacrificial template of as-prepared hierarchical $NaSbO_3$ precursor at 220 °C for 24 h (see Fig. 7). The as-prepared hierarchical $AgSbO_3$ (i.e., AgSb–HT) showed higher (1.8 times) photocatalytic activity for visible-light-driven O_2 evolution (initial rate, 460 μmol $h^{-1} g_{cat}^{-1}$) than $AgSbO_3$ formed by performing an ion exchange of Ag^+ on $NaSbO_3$ precursor prepared by a solid-state reaction (i.e., AgSb–SSR—36 h) (see Fig. 8). The unique structure of hierarchical cuboidal microclusters assembled from single-crystal nanosheets with exposed {001} facets simultaneously optimized all three main processes of the photocatalytic reaction (i.e, photon absorption, separation and migration of photogenerated charge carriers, and redox reaction of photogenerated charge carriers), and therefore enhanced the photocatalytic activity [112]. In addition, the sacrificial templates of microtubular (Cr,Ta)-codoped TiO_2 were prepared by solvothermal reaction and calcination post-treatment, and then were successfully transformed to nanocrystal-based microtubular (Cr,Ta)-codoped $SrTiO_3$ by hydrothermal reaction. The as-prepared hierarchical (Cr,Ta)-codoped $SrTiO_3$ also showed higher photocatalytic activity for visible-light-driven H_2 evolution than (Cr,Ta)-codoped $SrTiO_3$ formed by a solid-state reaction [114]. Consequently, the preparation strategy based on design and transformation of sacrificial templates is an effective method to construct special micro-/nano-structures; and the special micro-/nano-structure design is an effective route to enhance photocatalytic performance.

Besides, other preparation strategies (such as polymerized complex method and sol–gel route) were employed to obtain ABO_3 photocatalysts with special micro-/nano-structures (such as $SrTiO_3$ nanocrystals [72], La-doped $NaTaO_3$ nanocrystals [107], $LiNbO_3$ and $NaNbO_3$ nanowires [84,105]) and with enhanced photocatalytic activities.

Based on the above results, it was found that the micro-/nano-structures of ABO_3 photocatalysts could be adjusted by different preparation strategies, aiming to control the
Fig. 7 Schematic illustration of the growth mechanisms of NaSbO$_3$ and AgSbO$_3$ HCMCs during hydrothermal treatment in a drying oven at 250 °C, showing dissolution–redeposition–recrystallization and dehydration processes, followed by an ion-exchange reaction at 220 °C, which results in a topotactic transformation process. Coordinates are nonlinear. Reprinted with permission from Ref. [112].

physicochemical properties, such as crystallinity, crystal size, crystal orientation, surface area, and architecture, and therefore to optimize the whole photocatalytic process.

4.3. Local lattice structure adjustment

Local lattice structure is one of the important physicochemical properties of materials, and hence played a pivotal role in determining the photocatalytic performance. Correspondingly, the local lattice structure adjustment of ABO$_3$ photocatalysts will be introduced and the structure–activity relationship will be discussed in the following section.

4.3.1. Crystal structures

Crystal structures determined the symmetrical characteristics of crystals, and thus inevitably affected the local lattice structures and photocatalytic performance of materials [30–32,46,53,54,65,67,79].

The relationships between Ta–O–Ta bond angles and photocatalytic activities of ABO$_3$-based materials were comprehensively investigated by different research groups. Kato et al. prepared a series of alkali tantalate ATaO$_3$ (A=Li, Na, and K) photocatalysts that showed activities for overall water splitting under UV irradiation. The interaction between corner-sharing TaO$_6$ octahedra in ilmenite LiTaO$_3$ is so weak that the excited energy is localized because of a bond angle of Ta–O–Ta far from 180°. In contrast, the excited energy is delocalized in perovskite NaTaO$_3$ and KTaO$_3$ in which the bond angle are close to 180°. The high activity of NiO/NaTaO$_3$ photocatalyst was in part due to the delocalization of excited energy which were dominated by the slightly distorted connection between TaO$_6$ octahedra [46]. Teng et al. investigated the effects of crystal structures, especially the Ta–O–Ta bond angles, in NaTaO$_3$ on the photocatalytic activities in detail [30,65,79]. NaTaO$_3$ with monoclinic and orthorhombic phases were prepared by sol–gel and solid-state reaction, respectively. Compared with the orthorhombic NaTaO$_3$, the monoclinic NaTaO$_3$ showed higher photocatalytic activity for H$_2$ evolution due to the larger surface area and the advantageous features in the electronic and crystal structures. In terms of electronic structure, the monoclinic and orthorhombic phases had indirect and direct bandgaps, respectively. The recombination rate for the photogenerated charge carriers in the monoclinic phase would be much smaller because phonons are involved in the gap transition. In addition, the monoclinic phase was found to have a larger number of effective states available for the photogenerated charge carriers. As for crystal structure, the bond angle of Ta–O–Ta for orthorhombic phase was about 163° while that of the monoclinic phase was close to 180°, which was favorable for delocalization of the excited energy in NaTaO$_3$ [65]. The decrease of photoluminescence intensity with the increase of Ta–O–Ta bond angle directly evidenced that the Ta–O–Ta bond angle affects the separation of photogenerated charge carriers [79]. Furthermore, they improved the photocatalytic activity of NaTaO$_3$ by replacing some Na ions with larger K ions to produce Na$_{1-x}$K$_x$TaO$_3$ photocatalysts. K-doping at $x=0.05$ rectified the distorted perovskite NaTaO$_3$ to a pseudo-cubic phase. The 180° bond angle of Ta–O–Ta in the pseudo-cubic phase may facilitate the separation of photogenerated charges for effective water splitting. Further K-doping (with $x>0.05$) leads to impurity formation, which bends the Ta–O–Ta linkage and creates

defect states, lowering the photocatalytic activity of $Na_{1-x}K_x$-TaO_3 [31].

Besides, the correlation between phonon modes and photocatalytic activities of ABO_3-based $BaM_{1/3}N_{2/3}O_3$ (M = Ni, Zn; N = Nb, Ta) materials were suggested by Yin et al. The Nb-containing photocatalyst in each pair shows higher photocatalytic activity in evolving H_2 from the methanol solution under UV irradiation than the Ta-containing photocatalyst. Raman spectra of these pairs of photocatalysts suggest that some phonon modes in the bending branches for the Ta-containing photocatalyst show an obvious red shift in their frequency, compared with those for the corresponding Nb-containing photocatalyst. Consequently, phonon modes may play an important role in the migration of the photogenerated charge carriers, thus affecting the photocatalytic activity [54].

4.3.2. Site occupancy

Owing to the different local lattice environments of A and B sites, as for cations doped ABO_3 photocatalysts, the substitutional sites of doped cations were expected to have important influences on the photocatalytic activities.

Wang et al. prepared two Cr-doped $SrTiO_3$ photocatalysts, $(Sr_{0.95}Cr_{0.05})TiO_3$ with A-site substitution and $Sr(Ti_{0.95}Cr_{0.05})O_3$ with B-site substitution, and found that the H_2 evolution rate over $(Sr_{0.95}Cr_{0.05})TiO_3$ was 100 times more than that over $Sr(Ti_{0.95}Cr_{0.05})O_3$ from aqueous methanol solution under visible-light irradiation. Concerning the charge compensation, the Cr cations located at the Sr^{2+} site were Cr^{3+}, while those doped at the Ti^{4+} site were Cr^{3+} and Cr^{6+}. Cr^{6+} in $Sr(Ti_{0.95}Cr_{0.05})O_3$ behaved as recombination centers of photogenerated charge carriers and therefore reduces the photocatalytic activity. It was thus suggested that the valence states of doped multivalent cations in ABO_3 photocatalysts could be controlled by taking advantages of the charge balance and valence difference at A and B sites [39].

Kanhere et al. prepared a series of Bi-doped $NaTaO_3$ photocatalysts with different substitutional sites for Bi cations. On the one hand, the optical properties of Bi-doped $NaTaO_3$ were tuned by changing the substitutional sites, and Bi ions located at both Na and Ta sites resulted in the narrowest bandgap (2.64 eV). On the other hand, Bi ions at both Na and Ta sites helps maintain the ionic charge balance and thus minimize the native defects (such as oxygen vacancy and cation vacancy). Accordingly, Pt/Bi-doped $NaTaO_3$ with equal A- and B-site substitution was more active than those with either A- or B-site substitution for visible-light-driven H_2 evolution because of the optimized electronic structures for bandgap narrowing to absorb visible-light absorption and the favorable crystal structures for depressing lattice defects to reduce the recombination of photogenerated charge carriers [120].

In our recent work, aiming to mediate the contradiction between the utilization of low-energy photons (visible light) and the preservation of the redox abilities of photogenerated charge carriers and thus to provide a new route to develop single photocatalyst for overall water splitting under visible-light irradiation, upconversion luminescent agent doped ABO_3 were designed and prepared, and successfully applied to visible-light-driven photocatalytic H_2 and O_2 evolution. Furthermore, in order to promote the excitation of photogenerated charge carriers, site-selected doping was adopted to optimize the local lattice environment. A series of upconversion luminescent Er^{3+} doped $SrTiO_3$ photocatalysts with different initial molar ratios of Sr/Ti (i.e., $SrxTiy$–Er, Sr/Ti = x/y) have been prepared by a facile polymerized complex method. Er^{3+} ions, which were gradually transferred from the A to the B-site with increasing Sr/Ti, enabled the absorption of visible light by intraband transition and the generation of high-energy excited states by upconversion processes. Compared with those with A-site occupancy, Er^{3+} ions with B-site occupancy are located in distorted BO_6 octahedra with dipole moments and thus subject to much stronger local internal fields, which promotes energy transfer from the high-energy excited states of Er^{3+} to the host $SrTiO_3$ and facilitates the generation of charge carriers in the valence band and conduction band of the host $SrTiO_3$ (see Fig. 9). Consequently, Er-doped $SrTiO_3$ with B-site occupancy instead of A-site occupancy are validated as novel, stable, and efficient photocatalysts for visible-light-driven H_2 (rate, 46.23 µmol h^{-1} g_{cat}^{-1}) and O_2 evolution (initial rate, 44.23 µmol h^{-1} g_{cat}^{-1}) (see Fig. 10). The results generally suggest that the introduction of upconversion luminescent agent into host semiconductor is a promising approach to simultaneously harness low-energy photons and maintain redox ability for photocatalytic H_2 and O_2 evolution and that the local lattice environment of doped element greatly determines the photocatalytic activity [115].

The above results demonstrated that site-selected doping of cations into ABO_3 host is an effective route to improve the photocatalytic performance. However, it was noted that the substitutional sites should be appropriately selected depending

on the specific objectives, such as valence-state control, band-structure adjustment, or energy-transfer enhancement.

The effect of cation ordering in ABO$_3$-based Sr–Al–Nb–O double perovskite (SAN) on the photocatalytic activity was revealed by Iwakura et al. for the first time. SAN particles had a domain structure of completely B-site ordered (Sr$_2$AlNbO$_6$) and disordered (SrAl$_{0.5}$Nb$_{0.5}$O$_3$) phases. It was found that photocatalytic activities of SAN for the evolution of H$_2$ and O$_2$ respectively from aqueous solutions of methanol and AgF decreased with increasing the fraction of the ordered phase. These results suggested that the photocatalytic activity of ordered Sr$_2$AlNbO$_6$ should be lower than that of disordered SrAl$_{0.5}$Nb$_{0.5}$O$_3$, although the reason need to be clarified in future studies [89].

Wu et al. investigated the relationship between cation-filling and photocatalytic activity of A$_x$BO$_3$-based tunnel-structure materials for the first time. The catalytic efficiency decreases quasi-linearly with the A-site cation filling of the deficient perovskite A$_x$NbO$_3$ (A=K, Na, Sr, Ba) and the ideal perovskite ATiO$_3$ (A=Mg, Ca, Sr, Ba). A lower cation filling in the A-site correlates with higher mobility and improved the separation and transport of photogenerated charge carriers, and therefore resulted in higher photocatalytic activity. Moreover, the linear correlation also holds for the reported tunnel photocatalysts of Bi$_2$RNbO$_7$ (R=Y, rare earth element), MIn$_2$O$_4$ (M=Ca, Sr, Ba), ATaO$_3$ (A=Li, Na, K), etc. This study not only demonstrates that it is important to take cation filling into account when ranking activity of tunnel-structure photocatalysts, but also discloses some insights for developing new photocatalysts from crystal chemistry [141].

In addition to the control of crystal structures and site occupancy, other strategies such as surface modification were also employed to adjust the local lattice structures of ABO$_3$-based photocatalysts. Recently, Ouyang et al. successfully improved the activity of photocatalytic H$_2$ evolution over SrTiO$_3$-based photocatalysts by surface alkalinization. It was found that surface alkalization could significantly shift surface conduction band of SrTiO$_3$ photocatalyst to a more negative level, which supplies a strong potential for H$_2$O reduction and consequently promote the photocatalytic efficiency of H$_2$ evolution. This mechanism is also applicable for the visible-

light-sensitive (La,Cr)-codoped SrTiO$_3$. Hence this photocatalyst could achieve a high apparent quantum efficiency of 25.6% at around 425 nm for H$_2$ evolution in methanol aqueous solution containing 5 M NaOH [113].

4.4. Application of the modification strategy of ABO$_3$ photocatalysts in designing A$_x$B$_y$O$_z$ photocatalysts

In our recent work, aiming to enhance the visible-light-driven photocatalytic activity and apply the modification strategies of ABO$_3$ to A$_x$B$_y$O$_z$, A$_x$B$_y$O$_z$ with continuously adjusted chemical components and micro-/nano-structures were designed and prepared for visible-light-driven photocatalytic H$_2$ evolution. A series of cubic-phase pyrochlore structure tin(II) antimonate photocatalysts with continuously adjusted chemical components and micro-/nano-structures (i.e., SnSb–T $^\circ C$$t$h) were successfully prepared by facile ion-exchange processes with varied ion-exchange time (t) and temperature (T) on the antimonic acid precursor (HSb). With the increase of Sn^{2+} contents in as-prepared tin(II) antimonate photocatalysts, the extended light-response range due to the narrowed bandgaps enhanced the absorption of photons and the excitation of photogenerated charge carriers (see Fig. 11). The micro-/nano-structures were gradually transformed from regular octahedra around 100 nm to nanocrystallines with smaller sizes, and such nanostructural transformation gradually increased the BET surface areas and pore volumes. The decreased crystal sizes shortened the migration distance of photogenerated charge carriers to the reactive sites for redox reactions on the surfaces and thus reduced the recombination of photogenerated charge carriers; the increased BET surface areas enriched the reactive sites, and also enhanced the adsorption of reactants, while the enlarged pore volumes facilitated the accumulation of reactants as well, thereby accelerating the redox reactions. The approaching stoichiometric compositions (molar ratio of Sn/Sb equal to 1) reduced the crystal lattice defects to restrain the recombination of photogenerated charge carriers. Accordingly, the activities of visible-light-driven photocatalytic H$_2$ evolution were gradually improved and amounted to the highest rate of 40.10 μmol h^{-1} g$_{cat}^{-1}$ for stoichiometric Sn$_2$Sb$_2$O$_7$ (see Fig. 12). However, with the further increase of Sn^{2+} content, the activity sharply decreased due to the nonstoichiometric compositions that increased the crystal lattice defects to accelerate the recombination of photogenerated charge carriers, although the bandgaps and micro-/nano-structures seemed to be further optimized (see Fig. 12). As a result, the as-prepared tin(II) antimonates—especially Sn$_2$Sb$_2$O$_7$ were validated to be novel, stable photocatalysts for visible-light-driven H$_2$ evolution. The control of physicochemical properties based on continuous adjustment of chemical components and micro-/nano-structures is an effective approach to optimize all the processes of photocatalytic reaction and finally enhance photocatalytic activity. It is validated to apply the modification strategies of ABO$_3$ to A$_x$B$_y$O$_z$ based on the similarity between ABO$_3$ and other A$_x$B$_y$O$_z$ [142,143].

5. Application of ABO$_3$ photocatalysts in *Z*-scheme systems for overall water splitting

It is very difficult for a single-photocatalyst system to fulfill the requirements of a narrow bandgap for visible-light absorption
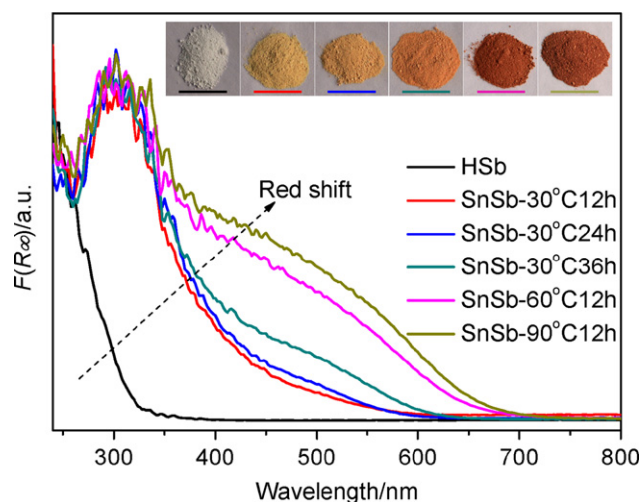

Fig. 11 UV/vis spectra of HSb and SnSb–T °Cth samples. Along the direction of the arrow: HSb, SnSb—30 °C12 h, SnSb—30 °C24 h, SnSb—30 °C36 h, SnSb—60 °C12 h, and SnSb—90 °C12 h. $F(R_\infty)$ was the Kubelka–Munk function. Reprinted with permission from Refs. [142,143].

and suitable band-edge positions for redox reactions simultaneously. Consequently, single photocatalysts for overall water splitting under visible-light irradiation are rarely reported to date. Z-scheme system mimics the photosynthesis process of green plants, and is composed of a photocatalyst for H_2 evolution (i.e., H_2-photocatalyst), a photocatalyst for O_2 evolution (i.e., O_2-photocatalyst), and electron mediator (not indispensable). Based on a two-photon process in the Z-scheme system, photocatalysts with solely ability to evolve H_2 or O_2 from the corresponding sacrificial reagents under visible-light irradiation could be coupled effectively, thus realizing visible-light-driven overall water splitting [24].

As discussed above, a variety of ABO_3 structure-based photocatalysts for half-reaction of H_2 or O_2 evolution under visible-light irradiation were developed by means of different modification strategies. Accordingly, ABO_3 photocatalyst-based

Z-scheme systems could be constructed to realize visible-light-driven overall water splitting (see Table 2). The electron mediators in the Z-scheme system play important roles in coupling the two H_2- and O_2-photocatalysts, respectively, and in shuttling the photogenerated carriers. The currently developed Z-scheme systems could be classified as those with ionic electron mediators, with solid electron mediators, and without electron mediators.

5.1. Z-scheme systems with ionic electron mediators

Ionic electron mediators in Z-scheme systems included IO_3^-/I^- [99,144,146,150,153], Fe^{3+}/Fe^{2+} [147,149,151], etc. Sayama et al. reported the first Z-scheme system (Pt/(Cr,Ta)-codoped $SrTiO_3$|Pt/WO_3) for visible-light-driven overall water splitting by using Pt/(Cr,Ta)-codoped $SrTiO_3$ and Pt/WO_3 as H_2 and O_2-photocatalysts, respectively, and by using IO_3^-/I^- as electron mediator. The AQY was determined to be ca. 1% at 420 nm [144–146]. Hara and Irie prepared two types of $SrTiO_3$-based photocatalysts, (Bi,Ga)-codoped $SrTiO_3$ and (In,V)-codoped $SrTiO_3$, both of which formed isolated mini-bands in the forbidden band and thus could absorb visible light. Furthermore, they established a Z-scheme system (Pt/(Bi,Ga)-codoped $SrTiO_3$|Pt/(In,V)-codoped $SrTiO_3$) by using the as-prepared $SrTiO_3$-based photocatalysts and IO_3^-/I^- electron mediator. It was found that visible light contributed to overall water splitting and enhanced the photocatalytic activity [153]. In addition to doped ABO_3 photocatalysts, ABO_3-based solid-solution photocatalysts were employed to construct Z-scheme system as well [99,150]. Matoba et al. prepared $BaZrO_3$–$BaTaO_2N$ solid solution, which was coupled with WO_3 to form a Z-scheme system (Pt/$BaZrO_3$–$BaTaO_2N$ solid solution/Pt/WO_3) in IO_3^-/I^- solution. The AQY for overall water splitting was calculated to be about 0.6% at 420–440 nm [99].

In addition to IO_3^-/I^-, Fe^{3+}/Fe^{2+} was also widely employed to construct Z-scheme systems. Sasaki et al. built a Z-scheme system consisting of Rh-doped $SrTiO_3$ for H_2 evolution, $BiVO_4$ for O_2 evolution, and Fe^{3+}/Fe^{2+} for an electron mediator, and investigated the effect of cocatalysts loaded on Rh-doped $SrTiO_3$ on photocatalytic reaction. It was found that compared with the system using a Pt cocatalyst (Pt/Rh-doped $SrTiO_3$|$BiVO_4$), the system using a Ru cocatalyst (Ru/Rh-doped $SrTiO_3$|$BiVO_4$) showed comparable activity in the initial stage but exhibited no deactivation process for visible-light-driven overall water splitting. The back-reactions, such as, water formation from H_2 and O_2, reduction of Fe^{3+} by H_2, and oxidation of Fe^{2+} by O_2 were significantly suppressed in the system of Ru/Rh-doped $SrTiO_3$|$BiVO_4$, which gave an AQY of 0.3% [147]. Alternatively, in order to realize the separation of evolved H_2 and O_2 and thus to prevent back-reactions in the Z-scheme system of Pt/Rh-doped $SrTiO_3$|$BiVO_4$, Yu et al. designed a twin reactor with a Nafion membrane to divide H_2- and O_2-photocatalysts in two compartments, respectively. It was found that the water-splitting reaction in the twin reactor did not delayed by the membrane through which the electron mediator of Fe^{3+}/Fe^{2+} was diffused, and the deactivation of Pt/Rh-doped $SrTiO_3$ could be minimized due to the suppression of $Fe(OH)_3$ formation on the photocatalyst surface [151].

Table 2 ABO$_3$-based Z-scheme system for overall water splitting.

H$_2$-photocatalyst (mass/g)|O$_2$-photocatalyst (mass/g)	Lamp (filter)[a]	Reactant solution (aqueous)	Activity/μmol·h^{-1}·g$_{cat}^{-1}$		AQY/% (wavelength/nm)	Reference (year)

^{a}The lamp (with filter if necessary) was used as light source.
^{b}The rate unit of gas evolution is μmol h^{-1}.

5.2. Z-scheme systems with solid electron mediators

Although ionic electron mediators performed efficiently in relaying electrons, a solid electron mediator is more favorable in terms of recovery of the photocatalyst and reclamation of clean water. Tada et al. designed the first all-solid-state Z-scheme system of CdS/Au/TiO$_2$ by using metallic Au as a solid electron mediator [154]. Using photoreduced graphene oxide (PRGO) as solid electron mediator, Iwase et al. coupled the photocatalysts of Rh-doped SrTiO$_3$ (SrTiO$_3$:Rh) for H$_2$ evolution and BiVO$_4$ for O$_2$ evolution to construct a novel Z-scheme system of Ru/Rh-doped SrTiO$_3$|BiVO$_4$ [152]. It was demonstrated that PRGO could shuttle photogenerated electrons from BiVO$_4$ to Rh-doped SrTiO$_3$ (see Fig. 13). The PRGO prepared by BiVO$_4$ possesses a high electron conductivity and a low degree of hydrophobicity, thus guaranteeing the efficient electron transfer and tripling the water splitting reaction under visible-light irradiation. An AQY of 1.03% at 420 nm was achieved in the Z-scheme system for overall water splitting.

5.3. Z-scheme systems without electron mediators

Generally, an electron mediator is required to construct a Z-scheme system. However, the affinity and energy-level matching between photocatalysts and electron mediators actually limit such a combination to several systems. Moreover, the electron mediators may give undesirable effects such as back-reactions to form water from H$_2$ and O$_2$ evolved, or their intermediates

to shield incident light. In order to exclude the negative effects by electron mediators and to simplify the design, Sasaki et al. fabricated the first Z-scheme system (Ru/Rh-doped SrTiO$_3$|-BiVO$_4$) driven by the interparticle electron transfer between two photocatalysts without an electron mediator for visible-light-driven overall water splitting (see Fig. 14). It was found that the photocatalytic activities were dependent on pH and the highest activity was obtained at pH 3.5, under which the two photocatalysts of Ru/Rh-doped SrTiO$_3$ and BiVO$_4$ were aggregated with suitable contact. Such intimate contact and the Rh species with reversible redox properties in Rh-doped SrTiO$_3$ facilitated the interparticle electron transfer from the conduction band of BiVO$_4$ to impurity level of Rh-doped SrTiO$_3$, and therefore improved the photocatalytic activity. The AQY of the Ru/Rh-doped SrTiO$_3$|BiVO$_4$ system was 1.7% at 420 nm [148].

The above results announced that the Z-scheme system paved an alternative way to visible-light-driven overall water splitting by using ABO$_3$ structure-based photocatalysts and verified the values of the ABO$_3$ structure-based photocatalysts that could only evolve H$_2$ or O$_2$ in corresponding sacrificial reagents.

6. Summary and perspectives

In summary, major progress on the development of ABO$_3$-based photocatalysts for water splitting has been achieved by means of different modification strategies based on the fundamental principle and process of photocatalysis and on

the crystal structure and chemical component characteristics of ABO₃ materials. The results demonstrated the encouraging prospects of ABO₃-based photocatalysts and offered a guide for future research work.

ABO₃ photocatalysts with typical crystal structures and chemical components, such as SrTiO₃ and NaTaO₃, have important research values as model photocatalysts to reveal the structure–activity relationships. Early in 1976, SrTiO₃ was proved to be an excellent photocatalyst for overall water splitting under UV irradiation due to its high stability and suitable band-edge positions [155], and, since then, has been extensively investigated by optimizing, for example, the reactant solution [123], cocatalyst [125,126,128,156,157], preparation method [127], and defects [81]. The reported results provided abundant data for future research on photocatalytic mechanism.

Modification of ABO₃ photocatalysts by combining different modification strategies is favorable for optimizing the whole process (i.e., absorption of photons and excitation of the photogenerated charge carriers, separation and migration of the photogenerated charge carriers, and redox reactions) during photocatalytic reaction, and finally improved the photocatalytic performance.

Development of ABO₃-based photocatalysts for overall water splitting under visible-light irradiation remains a great challenge but is still promising if appropriate strategies, such as the incorporation of upconversion luminescent agents (Er, Ho, Eu, Nd, Tm, and so on) and the construction of Z-scheme system, is employed. As for Er-doped SrTiO₃ [115], both abilities to produce H₂ and O₂ in corresponding sacrificial reagents under visible-light irradiation testified to the fulfilment of thermodynamic conditions for visible-light-driven overall water splitting. Further systematic and detailed work on the improvement of dynamic conditions (such as separation and migration of photogenerated charge carriers, and redox reactions), by optimizing reactant solution and
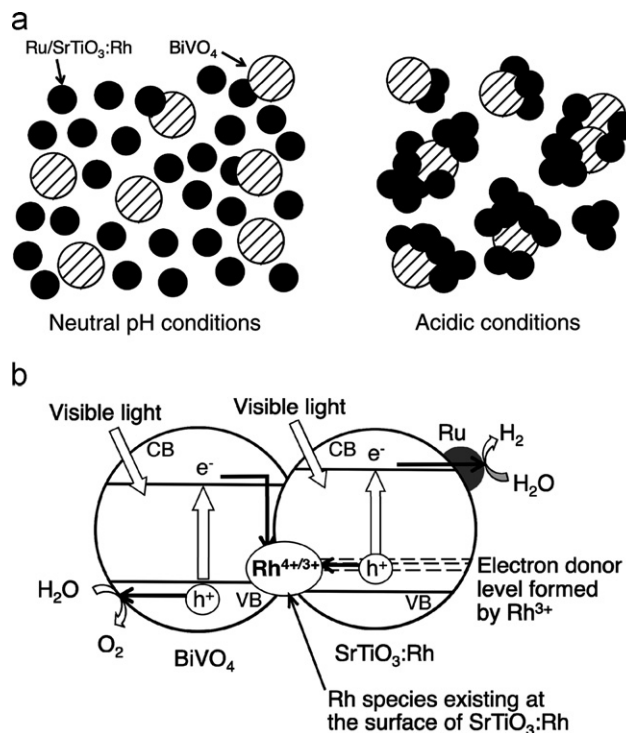

cocatalyst, is in progress in our group in order to realize overall water splitting under visible-light irradiation.

Preparation of ABO₃ film photocatalysts is favorable for photoelectrochemical characterization and performance evaluation so that more physicochemical properties can be obtained for more comprehensive understanding of ABO₃ powder photocatalysts. Furthermore, novel preparation strategies need to be developed due to the challenge of multi-component metal oxide films.

Prof. Dr. Liejin Guo is the director of the State Key Laboratory of Multiphase Flow in Power Engineering in Xi'an Jiaotong University, China. He obtained his PhD Degree in Power Engineering and Engineering Thermophysics from Xi'an Jiaotong University in 1989. His research interest includes multiphase flow, heat and mass transfer, and renewable energy technologies. He serves in the editorial boards of several international journals such as International Journal of Hydrogen Energy, International Journal of multiphase flow and Applied Thermal Engineering. He has published more than 400 papers in journals and conferences, given over 30 invited or keynote lectures in international conferences. He has been awarded with the Second Class Prize of National Natural Science Award in 2007 and the Second Class Prize of National Technology Innovation Award in 2009.
