Correlations

ABSTRACT

We consider the initial energy density in the transverse plane of a high energy nucleus–nucleus collision as a random field $\rho(\mathbf{x})$, whose probability distribution $P[\rho]$, the only ingredient of the present description, encodes all possible sources of fluctuations. We argue that it is a local Gaussian, with a short-range 2-point function, and that the fluctuations relevant for the calculation of the eccentricities that drive the anisotropic flow have small relative amplitudes. In fact, this 2-point function, together with the average density, contains all the information needed to calculate the eccentricities and their variances, and we derive general model independent expressions for these quantities. The short wavelength fluctuations are shown to play no role in these calculations, except for a renormalization of the short range part of the 2-point function. As an illustration, we compare to a commonly used model of independent sources, and recover the known results of this model.

1. Introduction

The fluctuations of the initial energy density (to be denoted $\rho(\mathbf{x})$ throughout this paper) in the transverse plane of a heavy ion collision play an essential role in the dynamics of these collisions. They leave observable traces in particle distributions after the hydrodynamical evolution [1]. They are for instance responsible for elliptic flow fluctuations [2,3] triangular flow [4–7] and higher harmonics [8,9], directed flow near midrapidity [9–12], and may also explain [13,14] observed transverse momentum fluctuations [15–18]. Considerable experimental and theoretical efforts are presently devoted to pin down the details of these fluctuations [19–22] and their various correlations [5,23,24].

It is then a natural question to try and specify the nature of the information that one can extract from measurements of various features of anisotropic flows. The initial energy density fluctuations are of several origins. The most prominent ones are usually attributed to the motion of individual nucleons in the nuclear wave-functions, and treated by Glauber Monte Carlo calculations [25–28]. In addition, there are sub-nucleonic fluctuations, that reflect the partonic structure of the colliding objects [29]. In most approaches, such sub-nucleonic fluctuations are added on top of the geometrical ones, using various “recipes” [30,31]. There is considerable ambiguity in the whole procedure: sources, with various locations [32], strengths [30], spatial extents, shapes, etc., are

added by hand to an already crude description of the nuclear wave-functions. It would certainly be desirable to use a description where all irrelevant details do not stand prominently.

We find it useful then to address the question from another angle, with the goal of obtaining general, model independent, statements about the fluctuations. To achieve this goal, we regard the energy density $\rho(\mathbf{x})$ in the transverse plane as a random field, and try to characterize the underlying probability distribution, $P[\rho]$ for finding a given $\rho(\mathbf{x})$ in a particular event. This probability distribution is the only ingredient of the description, and it encodes all sources of fluctuations, irrespective of their natures. We conjecture that this distribution is a local Gaussian with a short-range 2-point function. That is, we argue that the fluctuations of the density at different points in the transverse plane are essentially uncorrelated. Corrections are to be expected in regions where the nuclear density is low, and these corrections will be qualitatively discussed. Furthermore, we also argue that short wavelength fluctuations are irrelevant for the calculations of the eccentricities that drive the anisotropic flows, except for a small renormalization of the short range 2-point function.

We start, in the next section, by deriving general expressions for the eccentricities and their variances, in terms of the average density and the 2-point function of the probability distribution. The calculation exploits the fact that the relevant fluctuations have a small amplitude, relative to the average density. We then provide a simple ansatz for the 2-point function, which is dominated by a short range contribution. We compare results obtained with this

* Corresponding author.

ansatz with those obtained with a model of independent sources, and we recover known analytic formulas expressing the eccentricities as products of geometrical factors by an overall measure of the strength of the fluctuations. We then discuss why the Gaussian distribution provides a simple, and presumably realistic, form for the probability distribution.

2. Expressions of fluctuation observables in terms of the two-point function

We characterize event classes by the impact parameter \mathbf{b} . Even though not directly accessible experimentally, the impact parameter is well defined in a high energy collision. For simplicity, in most of this paper, we restrict ourselves to the case of central collisions, i.e. $\mathbf{b} = 0$, except for a remark on the general case at the end of this section. We write the energy density in a given event class as $\rho(\mathbf{x}) = \langle \rho(\mathbf{x}) \rangle + \delta\rho(\mathbf{x})$, where $\langle \rho(\mathbf{x}) \rangle$ is the average energy density and $\delta\rho(\mathbf{x})$ is referred to as the fluctuation. The probability that a given $\rho(\mathbf{x})$ occurs in the event class considered is denoted by $P[\rho]$.

The observables that we wish to calculate characterize the shape of the fluctuating density $\rho(\mathbf{x})$, in terms of its moments, commonly referred to as eccentricities [10]. These are defined by

$$\mathbf{e}_n \equiv \int_z z^n \rho(z). \quad (1)$$

Note that \mathbf{e}_n is a vector in the transverse plane (i.e., the plane transverse to the collision axis). In the right hand side of Eq. (1) we use the complex notation to represent vectors in the plane. That is, we allow for a slight abuse of notation and denote indifferently a vector \mathbf{r} by its components x, y , or by the complex number $z = x + iy$. Thus the density, denoted indifferently by $\rho(\mathbf{r})$ or $\rho(z)$, is a real function of x and y . Similarly, we use the short hand $\int_z = \int dx dy$ for the integration over the transverse plane.

The zeroth and first moments are special and require specific definitions:

$$\mathbf{e}_0 = \int_z |z|^2 \rho(z), \quad \mathbf{e}_1 = \int_z z^2 \bar{z} \rho(z), \quad (2)$$

with \bar{z} denoting the complex conjugate of z . The zeroth moment \mathbf{e}_0 is the mean squared radius of the density, while \mathbf{e}_1 is a measure of the dipole moment of the distribution [10]. The particular weight $z^2 \bar{z}$ in the integral defining \mathbf{e}_1 , instead of the more natural one, z , is due to the fact that in a centered coordinate system, to be defined shortly, the dipole moment vanishes (Eq. (3) below).

By definition, we call “centered” a coordinate system where

$$\int_z z \rho(z) = 0. \quad (3)$$

It is only in such a system that the definitions (1) and (2) above are valid. In a fixed coordinate system, however, the fluctuating density would be centered around a random point z_0 , distinct from the origin,

$$z_0 = \frac{\int_z z \rho(z)}{\int_z \rho(z)}, \quad (4)$$

and the definitions above need to be modified accordingly:

$$\begin{aligned} \mathbf{e}_0 &= \int_z |z - z_0|^2 \rho(z), & \mathbf{e}_1 &= \int_z (z - z_0)^2 (\bar{z} - \bar{z}_0) \rho(z), \\ \mathbf{e}_n &= \int_z (z - z_0)^n \rho(z). \end{aligned} \quad (5)$$

Because z_0 is a functional of ρ , Eq. (4), the averages of the eccentricities are in general difficult to evaluate. However, simple expressions can be obtained in the regime of small fluctuations, which is the case of practical interest. Indeed the calculation of the eccentricities \mathbf{e}_n , with n small, involves only the lowest (small \mathbf{k}) Fourier coefficients $\delta\rho_{\mathbf{k}}$ of the fluctuation $\delta\rho(\mathbf{r}) = \int_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{r}} \delta\rho_{\mathbf{k}}$ [10]. This automatically eliminates the rare fluctuations where $\delta\rho(\mathbf{r})$ can be locally large (spikes). We return to this issue in the next section.

We then assume that, for the long wavelength fluctuations, $\delta\rho(z) \ll \langle \rho(z) \rangle$, and choose the coordinate system such that $\langle \rho(z) \rangle$ is centered; in particular, at vanishing impact parameter, $\langle \rho(z) \rangle$ has azimuthal symmetry. The center of mass of $\rho(z)$ is still given by Eq. (4) with $\rho(z)$ in the numerator replaced by $\delta\rho(z)$: it follows therefore that z_0 differs from the origin of the coordinate system by a small amount, of order $\delta\rho/\langle \rho \rangle$. A simple calculation then yields, to linear order in the fluctuation,

$$\begin{aligned} \mathbf{e}_0 &= \int_z |z|^2 [\langle \rho(z) \rangle + \delta\rho(z)], & \mathbf{e}_1 &= \int_z [z^2 \bar{z} - 2\langle r^2 \rangle z] \delta\rho(z), \\ \mathbf{e}_n &= \int_z z^n \delta\rho(z), \end{aligned} \quad (6)$$

where we have set

$$\langle r^2 \rangle \equiv \frac{\int_z |z|^2 \langle \rho(z) \rangle}{\int_z \langle \rho(z) \rangle}, \quad (7)$$

and we have used symmetries of $\langle \rho(z) \rangle$ to eliminate some terms.

The anisotropic flow coefficients \mathbf{v}_n that are experimentally measured, are not directly related to the \mathbf{e}_n 's, but are rather proportional to the dimensionless ratios [2,10] defined, in a centered system, by

$$\mathbf{e}_n \equiv \frac{\int_z z^n \rho(z)}{\int_z |z|^n \rho(z)}, \quad \mathbf{e}_1 = \frac{\int_z z^2 \bar{z} \rho(z)}{\int_z |z|^3 \rho(z)}. \quad (8)$$

It has been shown indeed that the relation $\mathbf{v}_n \propto \mathbf{e}_n$, is well satisfied in ideal hydrodynamics [33–35], and even better so in viscous hydrodynamics [36]. Note that with the sign convention chosen in Eq. (8) (which differs from that in Ref. [10]) the response coefficients v_n/\mathbf{e}_n are *negative*. Similarly, we define \mathbf{e}_0 by dividing \mathbf{e}_0 by the total energy:

$$\mathbf{e}_0 = \frac{\int_z |z|^2 \rho(z)}{\int_z \rho(z)}. \quad (9)$$

This (dimensionful) quantity represents the mean square radius of the distribution in an individual event. It is distinct from (7) which involves the average density.

Expanding the scaled moments (8), (9) in powers of the fluctuation, we obtain, to leading order,

$$\mathbf{e}_0 = \langle r^2 \rangle + \frac{\int_z \delta\rho(z) (|z|^2 - \langle r^2 \rangle)}{\int_z \langle \rho(z) \rangle}, \quad (10)$$

and

$$\mathbf{e}_n = \frac{\int_z z^n \delta\rho(z)}{\int_z |z|^n \langle \rho(z) \rangle}, \quad \mathbf{e}_1 = \frac{\int_z [z^2 \bar{z} - 2z \langle r^2 \rangle] \delta\rho(z)}{\int_z |z|^3 \langle \rho(z) \rangle}. \quad (11)$$

Note that, at this order, only \mathbf{e}_0 contains a contribution unrelated to fluctuations, all eccentricities \mathbf{e}_n with $n \geq 1$, being entirely due to fluctuations for central collisions (the numerators of Eq. (11) are proportional to $\delta\rho$, the contributions of $\langle \rho \rangle$ being zero for symmetry reasons).

The situation is different at non-zero impact parameter. The calculations of the eccentricities for finite \mathbf{b} are straightforward extensions of those just presented for $\mathbf{b} = 0$, and lead to corrections to the formulas above. Just as an illustration, let us indicate the expressions of \mathbf{e}_2 and \mathbf{e}_3 at finite \mathbf{b} and to leading order in the fluctuation:

$$\mathbf{e}_2 = \frac{\langle z^2 \rangle}{\langle r^2 \rangle} + \frac{\int_z [z^2 - |z|^2 \langle z^2 \rangle / \langle r^2 \rangle] \delta \rho(z)}{\int_z |z|^2 \langle \rho(z) \rangle}, \quad \langle z^2 \rangle \equiv \frac{\int_z z^2 \langle \rho(z) \rangle}{\int_z \langle \rho(z) \rangle},$$

$$\mathbf{e}_3 = \frac{\int_z [z^3 - 3 \langle z^2 \rangle z] \delta \rho(z)}{\int_z |z|^3 \langle \rho(z) \rangle}, \quad (12)$$

where the averages are taken here for a non-vanishing impact parameter. Now, \mathbf{e}_2 also contains a correction independent of the fluctuation, whose physical interpretation is clear: the contribution $\langle z^2 \rangle / \langle r^2 \rangle$ represents the usual average eccentricity related to the “almond” shape of the collision zone. The odd harmonics, on the other hand, such as \mathbf{e}_3 , remain entirely due to fluctuations.

We return now to the case $\mathbf{b} = 0$. Since the eccentricities are linear in $\delta \rho$, their variances can be easily determined in terms of the two-point function of the probability distribution, defined as

$$S(z_1, z_2) \equiv \langle \delta \rho(z_1) \delta \rho(z_2) \rangle = \langle \rho(z_1) \rho(z_2) \rangle - \langle \rho(z_1) \rangle \langle \rho(z_2) \rangle. \quad (13)$$

Eq. (10) yields

$$\langle \Delta \mathbf{e}_0^2 \rangle = \frac{\int_{z_1 z_2} (|z_1|^2 - \langle r^2 \rangle)(|z_2|^2 - \langle r^2 \rangle) S(z_1, z_2)}{(\int_z \langle \rho(z) \rangle)^2} \quad (14)$$

while the mean square (ms) eccentricities are given by

$$\langle \Delta \mathbf{e}_n^2 \rangle = \langle \mathbf{e}_n \bar{\mathbf{e}}_n \rangle = \frac{\int_{z_1 z_2} z_1^n \bar{z}_2^n S(z_1, z_2)}{(\int_z |z|^n \langle \rho(z) \rangle)^2},$$

$$\langle \Delta \mathbf{e}_1^2 \rangle = \langle \mathbf{e}_1 \bar{\mathbf{e}}_1 \rangle$$

$$= \frac{\int_{z_1 z_2} (|z_1|^2 - 2 \langle r^2 \rangle)(|z_2|^2 - 2 \langle r^2 \rangle) z_1 \bar{z}_2 S(z_1, z_2)}{(\int_z |z|^3 \langle \rho(z) \rangle)^2}. \quad (15)$$

These formulas are general. They show that, in the regime of small fluctuations, the eccentricities and their variances are determined entirely by the average density and the two-point function of the probability distribution function $P[\rho]$.

3. Simple ansatz for the two-point function

At this point, it is instructive to consider a simple ansatz for the two-point function. This ansatz is motivated by considerations that will be discussed in the next section, as well as by the connection that it allows with simple models that have already been used to calculate the eccentricities. We assume that the two-point function is of the form

$$S(z_1, z_2) = A(z_1) \delta(z_1 - z_2) + B f(z_1) f(z_2), \quad (16)$$

where $\delta(z_1 - z_2) = \delta(x_1 - x_2) \delta(y_1 - y_2)$, and the dependence of A on z is through its dependence on $\langle \rho(z) \rangle$, in other words, A is a function of $\langle \rho(z) \rangle$. In Eq. (16), B is a constant and f some function, whose general determination is delayed till next section. However, an important practical case, as we shall see later, is $f(z) = \langle \rho(z) \rangle$. In this case the term proportional to B in Eq. (16) does not contribute to the variances (14) and (15). Inserting ansatz (16) into Eqs. (14) and (15) yields:

$$\langle \Delta \mathbf{e}_0^2 \rangle = \frac{\int_z A(z) (|z|^2 - \langle r^2 \rangle)^2}{(\int_z \langle \rho(z) \rangle)^2},$$

$$\langle \mathbf{e}_1 \bar{\mathbf{e}}_1 \rangle = \frac{\int_z (|z|^2 - 2 \langle r^2 \rangle)^2 |z|^2 A(z)}{(\int_z \langle \rho(z) |z|^3 \rangle)^2},$$

$$\langle \mathbf{e}_n \bar{\mathbf{e}}_n \rangle = \frac{\int_z |z|^{2n} A(z)}{(\int_z \langle \rho(z) |z|^n \rangle)^2}. \quad (17)$$

The function $A(z)$ is unknown at this stage. However, the success of the model of independent sources, that we shall introduce shortly, suggests that a linear dependence on the average density may be a good approximation. For this particular choice, namely $A(z) = A \langle \rho(z) \rangle$, with A constant, the formulas above simplify further:

$$\langle \Delta \mathbf{e}_0^2 \rangle = \frac{A}{\int_z \langle \rho(z) \rangle} [\langle r^4 \rangle - \langle r^2 \rangle^2],$$

$$\langle \mathbf{e}_1 \bar{\mathbf{e}}_1 \rangle = \frac{A}{\int_z \langle \rho(z) \rangle} \frac{\langle r^6 \rangle - 4 \langle r^4 \rangle \langle r^2 \rangle + 4 \langle r^2 \rangle^3}{\langle r^3 \rangle^2},$$

$$\langle \mathbf{e}_n \bar{\mathbf{e}}_n \rangle = \frac{A}{\int_z \langle \rho(z) \rangle} \frac{\langle r^{2n} \rangle}{\langle r^n \rangle^2}. \quad (18)$$

These formulas give the eccentricities as products of a “geometrical” factor that depends on the specific observable, and a dimensionless coefficient $A / \int_z \langle \rho(z) \rangle$, independent of the observable, that characterizes the magnitude of the local fluctuations of the energy density. At this point, it cannot be determined otherwise than by fitting the eccentricities to experimental data. However, further insight can be gained by considering the model of independent sources that we just alluded to.

This model can be viewed as a parametrization of the continuous energy density $\rho(z)$ in terms of “sources” [2,33,37]. One writes, typically

$$\rho(z) = E_0 \sum_{i=1}^{N_s} \delta(z - z_i), \quad \int_z \rho(z) = N_s E_0, \quad (19)$$

where z_i denotes the random location of a source, N_s the number of sources, and E_0 the energy of a source, taken here to be constant for simplicity. If one considers a class of events with a given transverse energy, then N_s is also a constant. In this case, the fluctuations are entirely due to the random positions of the sources in individual events. If the positions of these sources are uncorrelated, the 2-point function is proportional to that of independent particles in the plane. It reads

$$S(z_1, z_2) = E_0 \langle \rho(z_1) \rangle \delta(z_1 - z_2) - \frac{1}{N_s} \langle \rho(z_1) \rangle \langle \rho(z_2) \rangle. \quad (20)$$

This is a particular case of Eq. (16), with $A(z) = A \langle \rho(z) \rangle$, $A = E_0$, and $f(z) = \langle \rho(z) \rangle$, $B = 1/N_s$. Note that the second term in Eq. (20) ensures that fluctuations conserve the total number of sources, such that in particular $\int_{z_1 z_2} S(z_1, z_2) = 0$. This feature will be elaborated upon at the end of the next section. Here we simply notice that it affects only moderately the local fluctuations. To see that, let us assume for simplicity that the average density is constant on the transverse plane, and consider a small area $\sigma \ll \Sigma$, where Σ is the total area of the collision zone. From Eq. (20) one then easily deduces

$$\langle \delta \rho^2 \rangle = \frac{E_0}{\sigma} \langle \rho \rangle \left(1 - \frac{\sigma}{\Sigma} \right), \quad (21)$$

where $\langle \rho \rangle = E_0 N_s / \Sigma$. The last term in this expression, which originates from the second term in Eq. (20), is indeed negligible if $\sigma \ll \Sigma$. In this case, one recovers, for the number of sources in the area σ , $N_\sigma = \rho \sigma / E_0$, the variance characteristic of Poisson statistics, $\langle \delta N_\sigma^2 \rangle = \langle N_\sigma \rangle$. By increasing σ , one probes fluctuations of N_σ

over regions that are comparable to the total transverse area of the collision zone, that is, one looks at long wavelength density fluctuations. The distribution of N_σ becomes then a Gaussian, with a width $\propto \sqrt{\langle N_\sigma \rangle}$. The relative fluctuations are then small, with $\sqrt{\langle \delta \rho_\sigma^2 \rangle} / \langle \rho_\sigma \rangle = 1 / \langle N_\sigma \rangle \ll 1$, which confirms the validity of the expansion used in Section 2, based on the relative smallness of the amplitude of the long wavelength fluctuations.

More generally, we may characterize the strength of the fluctuations by the following ratio

$$\frac{\int_{z_1 z_2} A(z_1) \delta(z_1 - z_2)}{(\int_z \langle \rho(z) \rangle)^2} = \frac{E_0}{\int_z \langle \rho(z) \rangle} = \frac{1}{N_s}, \quad (22)$$

where, in the right hand side, we have used the 2-point function (20) of the source model. Thus, in this model, the dimensionless parameter that characterizes the magnitude of the fluctuations is the total number of sources: This is natural since, in this model, the fluctuations of the density are entirely determined by those of the locations of the sources. By substituting $1/N_s$ for the factor $A/\int_z \langle \rho(z) \rangle$ in Eqs. (18), one recovers the expressions derived in Refs. [38,37] (see also [39]). Note the ratio in Eq. (22), since it involves integrals over the transverse plane, provides a global characterization of the fluctuations. The numerator in Eq. (22) is the integral of the short range part of the correlation function $S(z_1, z_2)$ in Eq. (20). This is obviously equal to the integral of the second term, since, as already noticed, $\int_{z_1 z_2} S(z_1, z_2) = 0$.

The source model is much inspired by the participant picture of the nucleus–nucleus collisions, and the empirical proportionality between the transverse energy and the number of participants N_{part} [25]. Indeed, a comparison of the model with the Glauber Monte Carlo calculations reveals that the number of sources is of the order of that of the number of participants N_{part} (roughly one half [37]). However, in the present context, the proper interpretation of this model is that of a parametrization of a continuous field, the fluctuating density $\rho(z)$. In particular, there is a priori no reason to correlate rigidly the positions of the sources to those of the participants: in the model discussed above, these sources are located randomly in the collision area.

It should be emphasized that $A(z)$ need not be a simple linear function of $\langle \rho(z) \rangle$, as we have assumed in the second part of this section (and as it emerges naturally in the model of independent sources). In fact we have evidence that in nucleus–nucleus collisions, deviations from this simple behavior occur near the surface where the average density is small. For instance, Glauber Monte Carlo calculations suggest a specific type of correlations, that we dubbed twin correlations, which lead to a renormalization of the short range part of the two-point function [40]. For the sake of illustration, we take these into account by assuming that $\langle \rho(r) \rangle = \rho$ is uniform within a disk of unit radius, such that $\langle r^{2n} \rangle = R^{2n}/(n+1)$ (with $r = |z|$), and that A picks up an extra contribution near the surface, that is, we set $A(r) = \rho(1 + \alpha \delta(r/R - 1))$, with α a small parameter. Then, a simple calculation reveals that the variances $\langle |\mathbf{e}_1|^2 \rangle$, $\langle |\mathbf{e}_2|^2 \rangle$, $\langle |\mathbf{e}_3|^2 \rangle$ are corrected respectively by the factors 1 , $1 + 3\alpha$, $1 + 4\alpha$. The same ordering between \mathbf{e}_2 and \mathbf{e}_3 is observed in Monte-Carlo Glauber calculations [40].

4. The probability distribution

The simplest, least biased, picture for the fluctuations of the energy density in the transverse plane is that of independent fluctuations, with a probability distribution of the form

$$P[\delta \rho] \propto \exp \left\{ -\frac{1}{2} \int_{z_1, z_2} \delta \rho(z_1) K(z_1, z_2) \delta \rho(z_2) \right\}. \quad (23)$$

In this expression, the exponent may be seen as the analog of a Landau–Ginsburg free energy [41]. The kernel $K(z_1, z_2)$, which depends on the average local density, is the functional inverse of the two-point function $S(z_1, z_2)$:

$$\int_z K(z_1, z) S(z, z_2) = \delta(z_1 - z_2), \quad \langle \delta \rho(z_1) \delta \rho(z_2) \rangle = S(z_1, z_2), \quad (24)$$

and, as we shall argue soon, for all practical purposes, $K(z_1, z_2) \propto \delta(z_1 - z_2)$, and therefore also $S(z_1, z_2) \propto \delta(z_1 - z_2)$. The distribution (23) is then a local functional of $\delta \rho(z)$, describing uncorrelated fluctuations.

Aside from the fact that there is little evidence for deviations from this simple ansatz, there are microscopic arguments suggesting that energy density fluctuations are correlated only over short distances: At high energy, the processes dominating energy density production are semi-hard processes, and these take place locally, depositing energy over regions of sub-nucleonic sizes. In the Color Glass picture, for instance, the typical transverse size is of the order of the inverse of the saturation momentum Q_s [29]. This is also the distance over which fluctuations are correlated [42]. Correlations at the nucleon scale, inherited from the positions of the nucleons in each nuclei, are presumably not important: if one observes two fluctuations within a sub-nucleonic distance, it is likely that they originate from two nucleons that are separated longitudinally, and are therefore uncorrelated.¹

There is however another, perhaps stronger, argument in favor of the ansatz (23), with a short range kernel: short wavelength fluctuations are mostly irrelevant in the calculation of the eccentricities. In the extreme coarse-graining that is involved in such calculations, where only the smallest Fourier modes are retained, all what the short wavelength fluctuations do is renormalize the coefficient of the delta function contribution in $S(z_1, z_2)$, that is, the function $A(z)$ in Eq. (16). Since this is an important point, let us illustrate it by an elementary calculation. Let us return to the calculation of the eccentricities performed in the previous sections, and smear the delta function $\delta(z_1 - z_2)$ by a smooth, normalized, function $h(z_1 - z_1)$ peaked at small values of $|z_1 - z_2|$ (typically a Gaussian of width $\sigma = 0.4$ fm [14,33]). That is, let us set

$$S(z_1, z_2) = A(z) h(s), \quad z \equiv \frac{z_1 + z_2}{2}, \quad s \equiv z_1 - z_2, \quad (25)$$

and consider the calculation of $\langle |\mathbf{e}_n|^2 \rangle$. After performing the appropriate expansion that exploits the fact that in the integration $|s| \ll |z|$, we get

$$\int_{z_1 z_2} z_1^n z_2^n S(z_1, z_2) = m_n \left[1 - \frac{m_{n-1}}{m_n} \frac{n^2}{4} \int_s |s|^2 h(s) \right] \equiv m'_n, \quad (26)$$

where $m_n \equiv \int_z A(z) |z|^{2n}$ is the value of the integral when $h(s) = \delta(s)$. The finite range of h induces corrections that, for small n (in practice $n \leq 6$), are small, of order $[\int_s |s|^2 h(s)] / \Sigma$, with Σ the area of the collision zone. Furthermore, these corrections can be absorbed in a renormalization of the function $A(z)$, $A(z) \rightarrow A'(z)$, with the n th moment of $A'(z)$ equal to m'_n in Eq. (26) above. Thus the result is completely insensitive to the smearing of the short range 2-point function, provided the range of this smearing stays

¹ This argument has to be corrected as we move towards the surface of the collision zone, where the density is low, and twin correlations develop [40]. Recall, however, that these correlation simply renormalize the strength of the short range part of the correlation function (see the discussion at the end of Section 3).

small enough. These considerations also indicate that the measurements of the eccentricities cannot yield direct information on the “granularity” of the initial energy density [29,43,44], nor on the direct microscopic mechanisms responsible for the fluctuations: the eccentricities are sensitive only to the overall strength of the fluctuations, not to the details of what happens at short distance scales.

We now return to our ansatz for the 2-point function and comment on the second term in Eq. (16). This term reflects generically the long range correlations that originate from global constraints, such as for instance energy conservation, or recentering. Such constraints can be expressed generically in the form

$$\int_z \delta\rho(z)\phi(z) = 0. \quad (27)$$

Choosing for instance $\phi(z) = 1$ enforces $\int_z \delta\rho(z) = 0$ in each event (which corresponds to a selection of events with a given E_T), $\phi(z) = z$ enforces the centering of the fluctuations,² $\int_z z\delta\rho(z) = 0$, etc. Implementing such linear constraints on the probability distribution can be easily done by using the standard techniques of generating functionals and Lagrange multipliers. The resulting distribution is still a Gaussian, but the two-point function takes now the form

$$\langle \delta\rho(z_1)\delta\rho(z_2) \rangle = A(z_1, z_2) - \frac{[\int_{z_2} A(z_1, z_2)\phi(z_2)][\int_{z_1} \phi(z_1)A(z_1, z_2)]}{\int_{z_1 z_2} \phi(z_1)A(z_1, z_2)\phi(z_2)}, \quad (28)$$

where $A(z_1, z_2)$ denotes here the inverse of $K(z_1, z_2)$, i.e., the two-point function without the constraint. This equation is indeed of the form (16), with $f(z) \propto \int_{z'} A(z, z')\phi(z')$. For the constraint on E_T where $\phi(z) = 1$, and the choice $A(z) = E_0(\rho(z))$, with $\int_z \rho(z) = E_0 N_s$, we recover Eq. (20) of the main text.

Finally, it is worth emphasizing that a Gaussian distribution for the local fluctuations of the energy density does not preclude the existence of high-order cumulants for observables such as eccentricities, which would naturally explain the non-zero $v_3\{4\}$ observed in Pb–Pb collisions [5] and the non-zero $v_2\{4\}$ in p–Pb collisions [46,47] ($v_n\{4\}$ denotes as usual the fourth order cumulant of the flow coefficient v_n). In Section 2, we have expanded eccentricities to leading order in the density fluctuations. Within this approximation, eccentricity fluctuations are Gaussian, which implies in particular that eccentricity cumulants of order 4 and higher vanish for central collisions [45]. Beyond this linear approximation, non-Gaussian behaviors may appear [39,48,49], even if the underlying density fluctuations are Gaussian. A careful study of higher cumulants would reveal whether there exist non-trivial effects beyond those just mentioned, and would provide a more stringent test of the conjecture that the initial density fluctuations are Gaussian.

5. Summary

In summary, we have presented the first steps for a field theoretical description of the initial fluctuations of the energy density in the transverse plane of a high energy nucleus–nucleus collision. This description, free of irrelevant, model dependent details, rests

entirely on the probability distribution for the random field $\rho(\mathbf{x})$. We have presented arguments that suggest that this distribution is essentially a Gaussian with a short range 2-point function. We have obtained general expressions for the eccentricities that drive the anisotropic flows in terms of this 2-point function. We have shown that short wavelength fluctuations play no role in this calculation aside from renormalizing slightly the short range 2-point function. If, as we have argued, the basic correlations in the transverse plane occur at the sub-nucleonic level, with no other scale playing a major role all the way to the nuclear scale, the present description would hold for systems of all sizes, i.e., from AA to pA, till, why not, to large multiplicity pp.

² Note however that the procedure of modifying the probability distribution in order to deal only with centered density fluctuations is not equivalent to that used in Section 2 where we shift explicitly the observables by the center of mass z_0 of the fluctuation, and retain all fluctuations in the calculation. The latter procedure is the correct one to use in the present context.
