Factors predicting mitral restenosis after successful percutaneous mitral commissurotomy

Leila Bezdah [Orateur], Riadh Kasti, Meriem Drissa, Wafa Falah, W. Ouechtati, N. Haddad, Slim Sidhom, Hedi Baccar

Introduction: Percutaneous mitral commissurotomy (PMC) is the alternative treatment of choice for mitral stenosis (MS). Its immediate and medium term results are comparable to those of surgical commissurotomies, however in the long term there is a risk of restenosis. The purpose of this study is to determine the factors predicting restenosis after PMC.

Methods: 322 patients (66% women), average age: 35±13 years (9-75 years) having a tight MS and treated by PMC with Inoué balloon. The anatomic aspect of the mitral apparatus before PMC has been studied according to the criteria of the Wilkins score with a concomitant study of the state of the mitral commissures. The primary success of PMC is defined as follows: mitral area (MA) post-PMC >1.5 cm² and gain in MA >25% and mitral regurgitation (MR) ≤ grade 2. Mitral restenosis is defined as a MA <1.5 cm² and/or loss >50% of initial gain in MA.

Results: The rate of primary success of PMC was 86% and mean MA post PMC was 1.82±0.33 cm² compared to MA pre-PMC of 1±0.18 cm² (p<0.0001). Opening of two commissures has been observed in 74% of patients. After an average period of 62±32 months, only 12% of patients had a dyspnea stage III-IV of NYHA, MA was 1.64±0.3 cm² (p<0.001) and mitral restenosis happened in 47 patients (20%) after a period of 60.48±27 months (22-124 months).

The independent predictors of mitral restenosis after a successful PMC were: previous surgical commissurotomy, Wilkins score ≥8, MA after PMC <1.5 cm² and absence of bicommissural opening post PMC.

Conclusion: A favorable anatomy of mitral apparatus and the optimization of immediate result of PMC are the guaranty for the maintain of good result in the long term.

Closed mitral commissurotomy vs percutaneous mitral dilatation. Long term results in patients undergoing mitral valve replacement

Alaae Boutayeb [Orateur], Hicham Benyoussef, Chakib Benlaaquih, Loubna Chami, Malika Kettani, Ilham L mrabet, Wajih Maazouzi

Hôpital Ibn Sina, Chirurgie Cardiovasculaire, Rabat, Maroc

Background: In countries where still rheumatic heart disease, mitral stenosis is one of the most common valvulopathies. Mitral valve replacement is the gold standard, however, some patients can be eligible to closed surgical or percutaneous dilatations.

The aim of this study is to compare the long term results of both of techniques in patients undergoing mitral valve replacement.

Material and methods: This is a retrospective study including 35 patients who were operated for mitral valve replacement between Jan 2008 and Sept 2010. All of them have already undergone whether closed mitral commissurotomy (Group 1/25 patients) or percutaneous mitral commissurotomy (Group 2/10 patients).

Both the long term results of mitral dilatation, and, the short term outcomes of mitral valve replacement were studied.

Results: Events free survival was longer in CMC group (117 months vs 42 months). Mitral regurgitations observed in the first group (n=4) seemed to have rheumatic origin, whereas those observed in the second group (n=2) were iatrogenic.

Except bleeding, no difference was noted concerning the short term outcomes of the mitral valve replacement.

Conclusion: In spite of its invasiveness, closed mitral commissurotomy still an attractive therapeutic solution especially in rheumatic population. CMC results in good long term results and don’t compromise mitral valve replacement.

Aims: Although being a less invasive option than conventional surgery, TAVI procedures require large bore catheters, mini-invasive surgical access and double antiplatelet therapy. These factors might favour bleeding and negatively impact subsequent prognosis in these fragile patients with high comorbidities. We sought to evaluate the incidence, characteristics, predictors and prognosis impact of serious hemorrhagic complications following TAVI.

Methods: Between November 2008 and April 2011, n=112 consecutive patients with symptomatic severe aortic stenosis underwent TAVI in our institution (83.7±6.1 y; 39% men; mean Euroscore= 21.3±10.5) using either transfemoral and transapical access. The primary criteria was the incidence of any bleeding complication, according to recently proposed Valve Academic Research Consortium (VARC) criteria.

Results: Acute procedural success rate was 98%. Serious bleeding events were observed in 35% of patients, including n=15 VARC life-threatening/disabling (LT/D) and n=24 major bleeding events. Most of the complications were related to access site complications (71%).

Follow-up was achieved in n=106 patients (median follow-up =7.0 months range: 1-24). The mortality was significantly higher in patients with serious events compared to patient without bleeding (p=0.02, log-rank analysis). Although the survival didn’t significantly differ in patients with major hemorrhagic events (p=0.60), subjects with LT/D bleeding events had a higher mortality than the subjects with no hemorrhagic complications (p<0.001, log-rank analysis). Occurrence of VARC LT/D event following TAVI was a predictor of all-cause mortality (HR=6.1 [2.2-16.8], p<0.001) after adjustment for other variables in Cox regression analysis.

Conclusion: Serious bleedings are frequent following TAVI procedure and are mainly related to local haemorrhage. VARC life-threatening/disabling bleeding events have an impact on outcome and are associated with decreased survival after aortic stenosis correction.

Introduction: The wide use of PMC underlines the need to identify the predictive factors of restenosis to guide indications.

Materials and methods: retrospective study of 170 patients, hospitalized in the cardiology department between January 1994 and January 2008 having PMC by balloon inoue with a clinical and echocardiographic follow-up of more than 10 years.

Results: The restenosis was defined in our study by a mitral surface low than 1.5 cm², it was noted in 60 patients that is 35%. The estimation of Kaplan-Meier showed that the absence of restenosis was 87.6% in 3 years, 80% in 5 years, 72.4% in 7 years and 65.9% in 10 years. The predictive factors of restenosis identified by the univariate analysis were:

– History of PMC (p=0.017)
– Mitral valve area before PMC ≤ 0.8 cm² (p=0.089)
– A high echocardiographic score with a risk of restenosis multiplied by 5.5 if the score is ≥12(p=0.028)
– The mean pulmonary artery pressure before PMC>30 mmhg(p=0.089)
Methods: PMC by the Inoue balloon was attempted in 247 patients (mean age: 35 ans, 77% female) with severe mitral valve stenosis. All the patients had undergone echocardiographic examination before PMC to assess mitral anatomy, commissural calcification and to determine the Wilkins score.

Results: the mean value of Wilkins score was $7.98 \pm 1.61$ (range 5-13) and the mean mitral valve area (MVA) before PMC was $1 \pm 0.19 \text{ cm}^2$ (range 0.5-1.4 cm$^2$). Twenty-nine patients (11.7%) had one-commissural calcification. After PMC, the mean MVA increased to $1.79 \pm 0.34 \text{ cm}^2$ ($p<0.001$) resulting in a success rate of 83%. Severe mitral regurgitation (MR) occurred in 5 patients (2%). Wilkins score was an independent predictor of the immediate result of PMC, but if $>8$, this score had a weak predictive value. Commissural morphology was another independent predictor of the immediate result of PMC.

Conclusion: Echocardiography is now the cornerstone in the assessment of mitral anatomy before PMC and should integrate Wilkins score and commissural morphology for the optimal selection of patients to PMC.
