component of the cytoplasmic dynein biological motor complex has a relatively large number of interacting partners and fits the description of a hub. Partner proteins of LC8 include the intermediate chain (IC) subunit of cytoplasmic dynein, Chica, a mitotic spindle-associated protein, Nup159, a component of the yeast nuclear pore complex, and a wide array of proteins with roles in apoptosis, enzyme regulation and viral pathogenesis. Linear motifs mediate binding between LC8 and its partner proteins, but while partner proteins such as dynein IC have only one recognition motif, others such as Chica and Nup159 are enriched with multiple interacting motifs.

To better understand the importance of multiple recognition motifs in the LC8 interaction network, we have initiated structural and thermodynamic studies of the LC8/Chica and LC8/Nup159 complexes. Chica and LC8 have four and six putative recognition motifs respectively, nested within segments that are intrinsically disordered. Our results indicate that LC8 forms a dynamic complex with both proteins, binding only three (Chica) or five (Nup159) of the putative recognition motifs. Furthermore, we show that only three LC8 dimers are needed for optimal stability of the Nup159/LC8 complex, and suggest that the evolutionary adaptation of multiple LC8 recognition motifs imparts to the complex other properties such as rigidity. These findings extend the repertoire of functions of intrinsically disordered proteins to fine-tuning and versatile assembly of higher order macromolecular complexes.

Conformational Allostery in Nuclear Receptor/Coregulator Transcriptional Complexes
Ian M.S. De Vera, Douglas J. Kojetin.
The Scripps Research Institute, Jupiter, FL, USA.
By recruiting chromatin remodeling machinery to promoter regions of target genes, nuclear receptors (NRs) act as ligand-dependent transcriptional protein scaffolds, exerting powerful influences on all aspects of physiology. The critical mediators that bridge NRs to the transcriptional machinery are called NR coregulators. NR coregulators are broadly classified into coactivators and corepressors depending on their ability to promote or repress gene transcription. Coactivators contain a cluster of "LXXLL" motifs in a flexible/disordered region called the Receptor Interaction Domain (RID) that mediates their interactions with NRs. Because there is very little atomic level structural information on disordered coactivator RIDs, the physical mechanism driving the interaction between coregulator RIDs and NR transcriptional complexes is poorly understood. We are studying the interaction of Steroid Receptor Coactivator-2 (SRC-2) with the PPARγ-RXR transcriptional complex as a model system for understanding NR/coregulator interactions on the atomic level. SRC-2 is a critical coactivator in the PPARγ-driven differentiation of mesenchymal stem cells into fat cells, a pathway that is a target for therapeutic intervention of metabolic syndrome and type 2 diabetes. Using biochemical, biophysical and solution NMR approaches, we have begun to probe the interaction of the SRC-2 RID with the full-length PPARγ-RXR complex bound to DNA (~150 kDa complex). Our studies reveal that the binding of DNA to PPARγ-RXR imparts a long-range conformational change that impacts the binding and conformation of SRC-2 RID. Importantly, our work extends the recent proposition that DNA can act as an allosteric effector of NR activity, indicating that DNA binding can affect the conformation of a coregulator bound to a NR transcriptional complex.

Are Spider Silk Proteins a New Class of Intrinsically Disordered Proteins?
Dian Xu, Jeffrey L. Yarger, Gregory P. Holland.
Department of Chemistry and Biochemistry, Arizona State University, Tempe, AZ, USA.
Spider dragline silk is an outstanding biopolymer with a strength that exceeds steel by weight and a toughness greater than high-performance fibers like Kevlar. For this reason, understanding how a spider converts the gel-like, aqueous protein spinning dope within the major ampullate (MA) gland into a super fiber is of great importance for developing future biomaterials based on spider silk. In this work, the initial state of the silk proteins within the MA gland was probed with solution-state NMR spectroscopy following isotopic enrichment. 15N relaxation parameters, T1, T2 and 15N-(1H) steady-state NOE were measured for twelve backbone environments at two spectrometer frequencies, 500 and 800 MHz. All observed backbone environments are consistent with MA silk protein dynamics on the fast sub-nanosecond timescale. In addition, the observed conformation-dependent isotropic chemical shifts are consistent with a random coil. Therefore, it is concluded that the repetitive core of spider MA proteins are in an unfolded, highly flexible state in the MA gland. We propose that spider silk proteins can be considered intrinsically disordered proteins prior to fiber formation.

The nuclear hormone receptor androgen receptor (AR) is a transcription factor of 919 amino acids activated by androgens that regulates the development of the male sexual phenotype [1]. It is composed of three domains: a flexible N-terminal intrinsically disordered transactivation domain that interacts with the transcription machinery, a DNA-binding domain that binds specific DNA sequences adjacent to genes regulated by AR and a C-terminal domain that upon androgen binding undergoes a structural change that activates the protein. To understand the structural basis of transcription activation by the N-terminal domain of AR we have used NMR. We have in particular characterized the interaction between the N-terminal intrinsically disordered transactivation domain and the C-terminal domain of subunit 1 of TFIIH, a general transcription factor tightly associated with RNA polymerase and therefore considered part of the transcription machinery [2]. We find that this protein-protein interaction induces structure in an otherwise disordered region of sequence of this domain and have produced a structural model for the complex that we have validated both in vitro and in vivo. As we will show our results provide information about the mechanism by which AR activates transcription in castration resistant prostate cancer, a late stage of the disease for which there currently is no treatment.

The Intrinsically Disordered Photosystem II Subunit, PsbO, is a Sensor for the Hydrogen Bonding Network in the Oxygen Evolving Complex
Adam R. Offenbacher, Brandon C. Polander, Bridgette A. Barry.
Georgia Institute of Technology, Atlanta, GA, USA.
In Photosystem II (PSII), molecular oxygen is evolved from water after four sequential light-driven reactions, producing five oxidized states, Sn. PSII is composed of membrane-spanning subunits and an extrinsic subunit, PsbO. PsbO is intrinsically disordered and plays a role in facilitation of the water oxidizing cycle. Native PsbO can be removed and substituted with recombinant PsbO, thereby restoring steady-state activity. We used reaction-induced Fourier transform infrared (FT-IR) spectroscopy to obtain information concerning the role of PsbO during the S state cycle. Light-minus-dark difference spectra were acquired. A comparison of S minus S spectra demonstrated that amide frequency and intensity changes were associated with PsbO removal. These data suggest that PsbO acts as an organizational template for the PSII reaction center. To identify any coupled conformational changes arising directly from PsbO, global 13C PsbO isotope-editing was employed. The reaction-induced FT-IR spectra of accessible S states provided evidence that PsbO spectral contributions are temperature (263 and 277 K) and S state dependent. These experiments suggest that PsbO samples a rough conformational landscape when bound to its target, the photosystem II reaction center.

The Intrinsically Disordered Cytoplasmic Domain of the T-Cell Receptor Zeta Subunit Does not Form Disordered Dimers
Tanjia Mittag, Amanda Nourse.
St. Jude Children’s Research Hospital, Memphis, TN, USA.
Intrinsically disordered proteins play important roles in recognition, signal transduction and molecular sorting. They are generally thought to interact via coupled folding and binding, yielding largely ordered interfaces with their binding partners. In contrast, the intrinsically disordered cytoplasmic domain of the T-cell receptor zeta subunit (ζV) was reported to form homodimers with a dissociation constant of ~10μM in the absence of a disorder-to-order transition. This suggested the existence of highly disordered dimers. We show here using analytical ultracentrifugation that ζV is a disordered monomer up to at least millimolar concentrations. Paramagnetic relaxation enhancement demonstrates...
transient intra- rather than intermolecular interactions. Furthermore, even disul-fide crosslinking of $\zeta_{N-1}$ N-termini, in a configuration reminiscent of T cell receptor clustering, fails to lead to an association of protomers. SEC-MALS confirms the monomeric state of $\zeta_{N-1}$ but re-
veals a curious concentration-dependent shift of the elution volume of $\zeta_{N-1}$ that may previously have been interpreted as dimerization. Our data show that $\zeta_{N-1}$ does not form a highly disordered protein com-
plex but leave open the question as to whether completely disordered dimers or other oligomers exist in nature.

Mapping Residual Structure in Disordered Protein Ensembles with Millisecond H/D Exchange Mass Spectrometry
David D. Weis
Department of Chemistry, University of Kansas, Lawrence, KS, USA.
Interactions of intrinsically disordered proteins (IDP) with their binding part-
tners often involve coupled binding and folding. A long-standing question is the extent to which folding of the IDP is mediated by selection of a folded confor-
mer from the disordered state ensemble rather than folding induced by interaction with the binding partner. Answering this question requires detailed information about the disordered state ensemble, in particular the extent to which the IDP possesses residual structure. Yet obtaining this type of informa-
tion at near-atomic resolution remains challenging. To address this need, we have developed an approach based on millisecond quench-flow amide H/D exchange and mass spectrometry to measure residual structure. In the present work, we examine residual structure in the disordered CBP-binding domain of ACTR as a model system for validation. Following millisecond H/D exchange and acid quench, digestion with pepsin produced a set of 67 highly-overlapping fragments covering the entire 77-residue sequence. Residue-by-residue analysis of empirically-determined H/D exchange half-life obtained from each ACTR fragment provided exchange kinetics at near-
residue resolution.

In ACTR, we found that the regions that are known adopt an $\alpha$-helical fold upon binding to CBP became more protected from H/D exchange than the structured loop regions. We also found that most of the N-terminal region, which does not appear in the solved structure, was the least protected. There was also evidence of slight protection in a short stretch of the N-terminal region. Our results are consistent both with a recent analysis of residual structure obtained from NMR secondary shift measurements and with the AGADIR helicity prediction algorithm. Our results demonstrate the utility of millisecond H/D exchange for mapping secondary structural propensity in disordered state ensembles with near-residue resolution.

Structure and Internal Dynamics of Calcitonin Family Peptides: Implications for Amyloid Formation
Stephanie M. Cope1,2, Sara M. Sizemore1,2, Anindya Roy1, Giovanna Ghirlanda1, Sara M. Vaiana1,2, 1Department of Physics, Arizona State University, Tempe, AZ, USA, 2Center for Biological Physics, Arizona State University, Tempe, AZ, USA.
The calcitonin peptide (Ct) family comprises the intrinsically disordered pro-
teins amylin (IAPP), calcitonin gene-related peptide (CGRP), calcitonin, and adenomodulins. These are genetically and structurally related hormone pep-
tides that are able to bind to each other’s receptors, though with varying de-
grees of affinity. Some of these peptides form amyloid fibers, while others do not. They contain highly conserved sequence elements that have been exper-
imentally shown to affect the secondary structural preferences of these pep-
tides. The effect of such conserved elements on tertiary structure has not been experimentally explored to the same extent. Detecting tertiary structural properties of IDPs is considerably more challenging due to fast reconfigura-
tions of the backbone over a wide range of possible conformations. High res-
olution time-resolved techniques are needed. We use a nanosecond laser spe-
troscopy technique to examine transient tertiary contact formation. This technique reveals information on the structure and internal dynamics of IDPs. We compare members of the Ct family which differ in hydrophobicity and net charge, and study the effect of proline mutations on contact formation rates. We find that functionally required, conserved sequence elements play an important role in determining the structure, internal dynamics and aggre-
gation properties of these peptides.

Enantiospecific Recognition of the Intrinsically Disordered C-Myc Oncoprotein by Small Molecules
Kaitlyn P. Gerhart, Steven J. Metallo.
Chemistry, Georgetown University, Washington, DC, USA.
The prevalence of intrinsically disordered proteins (IDPs) in cell signaling and disease makes them attractive targets. Despite the absence of defined ter-
nary structures, many small molecules can bind IDPs at sites determined by a short, linear segment of the protein’s primary sequence. The oncoprotein c-Myc, a transcription factor that must undergo coupled folding and binding to its obligate partner Max in order to interact with DNA, is an attractive system for understanding specificity in small molecule binding to IDPs. Three inde-
pendent small molecule binding sites exist in the bHLHZip region of c-Myc, the segment necessary for coupled folding and binding to Max. The chiral small molecule 10074-A4 recognizes one of these sites. A racemic mixture of 10074-A4 exhibits a circular dichroism signal upon binding to c-Myc indicating an enatioselective interaction of the molecule with the protein. We provide a model for this induced circular dichroism signal based on conformational selection in the binding enantiomer, and we synthesize the pure enantiomers and compare their binding. Derivatives of 10074-A4 were synthesized and they also display enantiospecific binding. Even though c-Myc is disordered, and remains so in the complex, it specifically recog-
nizes both the chemical functionalities in the small molecule and their partic-
ular three dimensional arrangement.

Characterization of the Intrinsically Disordered Region of the Soluble Guanylate Cyclase Alpha-1 Subunit
Candice V. Benally, Parul Singh, Matthew J. Gage.
Northern Arizona University, Flagstaff, AZ, USA.
Soluble guanylate cyclase (sGC) is a heterodimeric protein, which is acti-
ated by nitric oxide, stimulating the conversion of guanosine triphosphate (GTP) to guanosine monophosphate (cGMP). Decreased sGC activity is linked to atherosclerosis, aging, loss of memory, acute ischemia, while increased sGC catalytic activity is associated with endothelial cell prolifera-
tion, vasodilation, cell motility and survival. The activation, catalytic activity and structure of sGC are widely studied, yet the site(s) involved in sGC regulation is not well understood. Soluble guanylate cyclase contains four distinct functional domains: the H-NOX, Per Arnt Sim, coiled-coiled and C-terminal catalytic domains. The H-NOX domain of the alpha-1 subunit also contains an intrinsically disordered region (IDR) whose role is not understood since it does not affect the dimerization or catalytic activity of the enzyme. Intrinsically disordered regions are regions that have no defined structure but retain function in a highly flexible state. These regions often undergo conformational changes upon protein-protein interactions. The human sGC IDR is predicted to be the first 69 residues of the alpha-1 subunit’s amino terminus but a similar region is not found on the beta-1 subunit. The goal of this study is to characterize the secondary structure of this IDR and probe for protein-protein interaction. The sGC IDR is predicted to contain about 20% alpha helical characteristics utilizing secondary structure prediction algorithms. Circular dichroism studies on the sGC IDR have shown that this region contains a small amount of stable helical structure. It also contains transient helical structure that can be stabilized by 2,2,2-tri-
fluoroethanol. Yeast two-hybrid studies are ongoing to identify interacting partners.

The Structural and Kinetic Ensemble of ASB9’s N-Terminus and It’s Role in Substrate Recognition
Jamie Schiffer, Deepa Balasubramaniam, Jonathan Parnell.
UC San Diego, San Diego, CA, USA.
Intrinsically disordered proteins (IDPs) have structural ensembles which lack stable tertiary and secondary structure under physiological conditions. IDPs have remodeled the structure-function paradigm, often participating in one-
to-one and many-to-many interactions. One class of IDPs which we have remained largely understudied are the ankyrin repeat and SOCS (suppressor of cytokine signaling) box containing proteins (ASBs). This class of proteins have an intrinsically disordered N-terminus, a six ankyrin repeat domain (ARD), and a C-terminal SOCS’s domain box. The SOCS box of ASB9 is
