Abstract

We calculate the mixed tensor susceptibility of QCD vacuum in the framework of the global color symmetry model. In our calculation, the functional integration over gluon fields can be performed and the gluonic vacuum observable can be expressed in terms of the quark operators and the effective gluon correlator. The mixed tensor susceptibility was obtained with the subtraction of the perturbative contribution which is evaluated by the Wigner solution of the quark gap equation. Using several different effective quark–quark interaction models, we find the values of the mixed tensor susceptibility are very small.

1. Introduction

In SVZ sum rules, in order to determine the static properties of hadrons it was suggested to consider two-point correlator functions of quark currents in the presence of an external constant classical field, where nonperturbative effects are taken into account in the so-called vacuum susceptibilities [1]. These induced condensates play important roles in determination of the hadron properties such as the nucleon magnetic moments [1], the isovector axial coupling constant [2–4], the isoscalar axial coupling constant [4], the pion–nucleon coupling constant [5] and the nucleon tensor charge [6,7] within this version of SVZ sum rules. In the literature, there are always two kinds of vacuum susceptibility that appear in the conventional two-point treatment of an external current field: one is the

induced quark condensate and the other is the induced mixed quark–gluon condensate. For convenience, we refer to the former as the quark condensate susceptibility and the later as mixed condensate susceptibility in this Letter.

The vacuum tensor susceptibilities are relevant for the determination of nucleon tensor charge [6,7]. The value of nucleon charge is related to the first moment of the transversity distribution $h_1(x)$, where $h_1(x)$ is an additional twist-two chirality violating structure function which can be measured in the Drell–Yan process with both beam and target transversely polarized. The previous evaluation of the quark condensate tensor susceptibility were performed in the framework of QCD sum rules [6–9], the chiral constituent model [10] and global color symmetry model (GCM) [11], respectively. Actually, there still exist uncertainty about this induced susceptibility since different theoretical treatments can give very different results, which should be checked by the future measurement of the transversity distribution $h_1(x)$. Another tensor susceptibility, the mixed condensate tensor susceptibility was only evaluated roughly in [6] within the two-point function of QCD sum rules.

GCM is a quark–gluon quantum field theory that very successfully models QCD for low energy hadronic processes [14–18]. In the framework of this truncated DSE model, the determination of the dimension 5 mixed quark–gluon condensate of QCD vacuum had been performed in [12] and the authors [13] had explored the thermal properties of this mixed condensate at finite temperature and chemical potential. In this Letter, a method to evaluate the mixed vacuum tensor susceptibility is proposed within the GCM formalism and the numerical results for the mixed tensor susceptibility are given.

2. Formalism

In a Euclidean space formulation, with $\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}$ and $\gamma_\mu^+ = \gamma_\nu$, the inverse of the dressed quark propagator at the chiral limit has the decomposition

$$G^{-1}(p) = i\gamma \cdot p + \Sigma(p) = i\gamma \cdot p A(p^2) + B(p^2), \quad (1)$$

where $\Sigma(p)$ stands for the dressing self-energy of quarks. Within the GCM formalism, the quark self-energy is determined by the rainbow-ladder truncated quark DSE

$$\Sigma(p) = \frac{4}{3} \int \frac{d^4q}{(2\pi)^4} g^2 D_{\mu\nu}(p-q) \gamma_\mu G(q) \gamma_\nu, \quad (2)$$

where $g^2 D_{\mu\nu}(p-q)$ is the effective gluon two-point function. It is important to appreciate that while the GCM has a formal global color symmetry, the detailed dynamical consequences of the local color symmetry of QCD are modelled by the particular form of $g^2 D(s)$. There is an infrared saturation effect which, in conjunction with the dynamical chiral symmetry breaking, appears to suppress details of the formal color gauge symmetry of QCD [17]. In the previous studies, various model forms for $g^2 D(s)$ [16–18] had been used for a variety of hadronic processes in the rainbow truncated DSE formalism. The phenomenon of the saturation effect is revealed by the fact that the forms of the solutions $A(s)$ and $B(s)$ at small s are insensitive to the detailed infrared form of $g^2 D(s)$ characterized by its large value at small s .

We will calculate the induced QCD vacuum condensates from the saddle-point expansion, that is, we will work at the mean field level. This is consistent with the large N_c limit in the quark fields for a given model gluon two-point function. For simplicity, the Feynman-like gauge $g^2 D_{\mu\nu}(x-y) = \delta_{\mu\nu} g^2 D(x-y)$ was adopted in our calculation and Eq. (2) takes the form

$$[A(p^2) - 1]p^2 = \frac{8}{3} \int \frac{d^4q}{(2\pi)^4} g^2 D(p-q) \frac{A(q^2)p \cdot q}{q^2 A^2(q^2) + B^2(q^2)}, \quad (3)$$

$$B(p^2) = \frac{16}{3} \int \frac{d^4q}{(2\pi)^4} g^2 D(p-q) \frac{B(q^2)}{q^2 A^2(q^2) + B^2(q^2)}. \quad (4)$$

In the chiral limit, there are two qualitatively distinct solutions in Eqs. (3) and (4). The “Nambu–Goldstone” solution characterized by $B(p^2) \neq 0$ describes a phase: (1) chiral symmetry is dynamically broken for it provides a momentum dependent constituent quark mass $M(p^2) = B(p^2)/A(p^2)$; and (2) the dressed quarks are confined for the dressed quark propagator does not have a Lehmann representation [18]. The alternative “Wigner” solution characterized by $B(p^2) \equiv 0$ describes a phase with neither dynamical chiral symmetry breaking nor confinement. In this Letter, we refer to the quark propagator in terms of the trivial solution of the gap equation as the “perturbative” quark propagator $G^{\text{per}}(p^2)$ with only the vector part

$$[A'(p^2) - 1]p^2 = \frac{8}{3} \int \frac{d^4 q}{(2\pi)^4} g^2 D(p-q) \frac{p \cdot q}{q^2 A'(q^2)}. \quad (5)$$

This “perturbative” quark propagator can be seen as the expectation value of the operator $T[q_i(x)\bar{q}_j(y)]$ over the perturbative vacuum $|P\rangle$ at the mean field level in the framework of GCM.

From the GCM generating functional, it is now straightforward to calculate the vacuum expectation value (VEV) of any quark operator of the form

$$\mathcal{O}_n \equiv (\bar{q}_{j_1} \Lambda_{j_1 i_1}^{(1)} q_{i_1}) (\bar{q}_{j_2} \Lambda_{j_2 i_2}^{(2)} q_{i_2}) \cdots (\bar{q}_{j_n} \Lambda_{j_n i_n}^{(n)} q_{i_n}), \quad (6)$$

in the mean field vacuum. Here the $\Lambda^{(i)}$ stands for an operator in Dirac, flavor, and color space. The VEV of the operator \mathcal{O}_n take the form [23]

$$\langle \mathcal{O}_n \rangle = (-1)^n \sum_p (-)^p [A_{j_1 i_1}^{(1)} \cdots A_{j_n i_n}^{(n)} G_{i_1 j_{p(1)}} \cdots G_{i_n j_{p(n)}}], \quad (7)$$

where p stands for a permutation of the n indices. Once the dressing quark propagator $G(q^2)$ is determined, one can calculate the two quark condensate $\langle \bar{q}q \rangle$, the four quark condensate $\langle \bar{q} \Lambda^{(1)} q \bar{q} \Lambda^{(2)} q \rangle$, etc., in the mean field level. Since the functional integration over the gluon field A_μ^a is quadratic in the framework of GCM, one can perform the integration over gluon field analytically. Using the same shorthand notation for the typical Gaussian integrations as in Ref. [12], we have

$$\begin{aligned} \int \mathcal{D}A e^{-\frac{1}{2}AD^{-1}A+jA} &= e^{\frac{1}{2}jDj}, & \int \mathcal{D}A A e^{-\frac{1}{2}AD^{-1}A+jA} &= (jD)e^{\frac{1}{2}jDj}, \\ \int \mathcal{D}A A^2 e^{-\frac{1}{2}AD^{-1}A+jA} &= [D + (jD)^2]e^{\frac{1}{2}jDj}, \end{aligned} \quad (8)$$

where D is the dressing gluon propagator and j_μ^a is the quark color current. Because the gluon vacuum average can be replaced by a quark color current $\bar{q}\gamma_\mu \frac{\lambda^a}{2}q$ together with the gluon two-point function D , one can perform the integration over the quark operators in the mean field vacuum as described above. In this way, one can in principle obtain the vacuum expectation of value for any gluonic fields. This technique provides an feasible way to evaluate the expectation value of the operators with low-dimensional gluon fields such as the mixed quark–gluon condensate $g\langle \bar{q}G_{\mu\nu}\sigma^{\mu\nu}q \rangle$ in GCM (note that for the VEV of operators with high powers of gluonic fields, this procedure will get rather complex).

3. Mixed tensor susceptibility

With above preparation, the mixed tensor susceptibility can be calculated in the mean field level within this DSE model. The induced tensor susceptibilities χ , κ and ζ are defined through

$$\langle V|\bar{q}\sigma_{\mu\nu}q|V\rangle_Z = g_q \chi Z_{\mu\nu} \langle \bar{q}q \rangle, \quad (9)$$

$$\langle V|\bar{q}g_c \frac{\lambda^a}{2} G_{\mu\nu}^a q|V\rangle_Z = g_q \kappa Z_{\mu\nu} \langle \bar{q}q \rangle, \quad (10)$$

$$\langle V | \bar{q} g_c \gamma_5 \tilde{G}_{\mu\nu} q | V \rangle_Z = -i g_q \zeta Z_{\mu\nu} \langle \bar{q} q \rangle, \quad (11)$$

where $Z_{\mu\nu}$ stands for the external field, $\langle V | \cdots | V \rangle_Z$ denotes the VEV over the QCD vacuum at the presence of the external field $Z_{\mu\nu}$ and $\tilde{G}_{\mu\nu} = \frac{1}{2} \frac{\lambda^a}{2} \epsilon_{\mu\nu\alpha\beta} G^{\alpha\beta a}$. The nonzero VEVs of the operators above are due to the breakdown of Lorentz invariance in the presence of external constant field $Z_{\mu\nu}$. From the QCD partition function for quarks in Euclidean space in the presence of the external field, the formulae for evaluating these susceptibilities take the form

$$\chi \langle \bar{q} q \rangle = \frac{1}{6} \int d^4x \langle V | T [\bar{q}(x) \sigma_{\mu\nu} q(x), \bar{q} \sigma_{\mu\nu} q] | V \rangle = \frac{1}{6} \Pi_\chi(0), \quad (12)$$

$$\kappa \langle \bar{q} q \rangle = \frac{1}{6} \int d^4x \langle V | T \left[\bar{q}(x) g_c \frac{\lambda^a}{2} G_{\mu\nu}^a q(x), \bar{q} \sigma_{\mu\nu} q \right] | V \rangle = \frac{1}{6} \Pi_\kappa(0), \quad (13)$$

according to Refs. [6,7]. Due to the fact that the vacuum susceptibilities reflect the nonperturbative structure of the QCD vacuum, $\Pi_\chi(0)$ and $\Pi_\kappa(0)$ on the right-hand side of Eqs. (12) and (13) should be subtracted by the corresponding perturbative contribution terms. Within the DSE formalism, the perturbative contribution to $\Pi_\chi(0)$ and $\Pi_\kappa(0)$ can be evaluated by the trivial quark propagator, namely the “perturbative” quark propagator in terms of the trivial Wigner solution to the dressed quark gap equations (3) and (4). This is a reasonable procedure because the Wigner solution of the dressed quark propagator describes a phase with neither DCSB nor confinement and the difference between the Nambu solution and the Wigner solution vanishes at short distance according to numerical studies. In fact, the Wigner solution has been used extensively to play the role of the perturbative dressed quark propagator in the study of thermal properties of QCD within the DSE formalism [18], where the bag constant was defined as the difference of the pressure between the true QCD vacuum and the perturbative QCD vacuum, which were evaluated by the Nambu–Goldstone solution and the Wigner solution to the quark propagator, respectively [19].

Therefore, we rewrite the Eqs. (12) and (13) as

$$\begin{aligned} \chi \langle \bar{q} q \rangle &= \frac{1}{6} \int d^4x \langle V | T [\bar{q}(x) \sigma_{\mu\nu} q(x), \bar{q} \sigma_{\mu\nu} q] | V \rangle^N - \frac{1}{6} \int d^4x \langle P | T [\bar{q}(x) \sigma_{\mu\nu} q(x), \bar{q} \sigma_{\mu\nu} q] | P \rangle^W \\ &= \frac{1}{6} \Pi_\chi^{np}(0), \end{aligned} \quad (14)$$

$$\begin{aligned} \kappa \langle \bar{q} q \rangle &= \frac{1}{6} \int d^4x \langle V | T \left[\bar{q}(x) g_c \frac{\lambda^a}{2} G_{\mu\nu}^a q(x), \bar{q} \sigma_{\mu\nu} q \right] | V \rangle^N \\ &\quad - \frac{1}{6} \int d^4x \langle P | T \left[\bar{q}(x) g_c \frac{\lambda^a}{2} G_{\mu\nu}^a q(x), \bar{q} \sigma_{\mu\nu} q \right] | P \rangle^W = \frac{1}{6} \Pi_\kappa^{np}(0). \end{aligned} \quad (15)$$

By substituting the “perturbative” quark propagator $G^{\text{per}}(p^2)$ to Eq. (7), the determination of the expectation value of the T-product operators in terms of quark fields over the perturbative vacuum state $|P\rangle$ can be performed self-consistently within the GCM formalism. It should be noted that the evaluation of $\chi \langle \bar{g} g \rangle$ in Ref. [11] is consistent with Eq. (14) because in this special case the subtraction terms to Eq. (14) has zero contribution to $\chi \langle \bar{g} g \rangle$ due to $B'(p^2) \equiv 0$.

Using Eq. (8), the expression for VEV of above T-product operator including gluonic fields is converted to the VEV for the product with the form of (6) in terms of six quark fields and eight quark fields. According to Eq. (7), we have

$$\begin{aligned} &\frac{1}{6} \int d^4x \langle V | T \left[\bar{q}(x) g_c \frac{\lambda^a}{2} G_{\mu\nu}^a q(x), \bar{q} \sigma_{\mu\nu} q \right] | V \rangle^N \\ &= -\frac{4}{3} i \int d^4x \int d^4z g^2 [\partial_\mu^x D(z-x)] \{ \text{tr}_D [G(x-z) \gamma_\nu G(z-0) \sigma_{\mu\nu} G(0-x)] \\ &\quad + \text{tr}_D [G(x-0) \sigma_{\mu\nu} G(0-z) \gamma_\nu G(z-x)] \} \end{aligned}$$

$$\begin{aligned}
& -2i \int dx^4 \int dz_1^4 \int dz_2^4 g^2 D(z_1 - x) g^2 D(z_2 - x) \\
& \times \left\{ \text{tr}_D [G(x - z_1) \gamma_\mu G(z_1 - z_2) \gamma_\nu G(z_2 - 0) \sigma_{\mu\nu} G(0 - x)] \right. \\
& + \text{tr}_D [G(x - z_1) \gamma_\mu G(z_1 - 0) \sigma_{\mu\nu} G(0 - z_2) \gamma_\nu G(z_2 - x)] \\
& \left. + \text{tr}_D [G(x - 0) \sigma_{\mu\nu} G(0 - z_1) \gamma_\mu G(z_1 - z_2) \gamma_\nu G(z_2 - x)] \right\}. \tag{16}
\end{aligned}$$

Substituting $G^{\text{per}}(x - y)$ for $G(x - y)$, the similar expression for the VEV of the same operator over the perturbative vacuum can be obtained. After Fourier transformation, we find that the first part of right-hand side of (16) is zero and the final result for the mixed tensor susceptibility in the momentum space takes the form

$$\begin{aligned}
\kappa(\bar{q}q) &= \frac{1}{16\pi^2} \int ds s \left[\frac{B(s)}{Z(s)} \right]^2 \left[\frac{27}{8} B^2(s) + \frac{27}{2} s A(s) (2 - A(s)) \right] \\
& - \frac{9}{32\pi^5} \int ds dt \int_{-1}^1 dx st \sqrt{1 - x^2} g^2 D(s, t, \sqrt{st}x) Z^{-2}(s) Z^{-1}(t) B(s) \\
& \times \left\{ B(s) B^2(t) + B(t) A(s) A(t) \sqrt{st}x - [A(s) - 1] [2A(s) B(t) \sqrt{st}x - A(t) B(s)] \right\} \\
& + \frac{3}{32\pi^5} \int ds dt \int_{-1}^1 dx st \sqrt{1 - x^2} g^2 D(s, t, \sqrt{st}x) \\
& \times (Z')^{-2}(s) Z'^{-1}(t) A'^2(s) A'(t) [A'(t) - 1] [st - 4stx^2] \\
& - \frac{3}{32\pi^5} \int ds dt \int_{-1}^1 dx st \sqrt{1 - x^2} g^2 D(s, t, \sqrt{st}x) \\
& \times Z^{-2}(s) Z^{-1}(t) A^2(s) A(t) [A(t) - 1] [st - 4stx^2], \tag{17}
\end{aligned}$$

where $Z(s) = sA^2(s) + B(s)$ and $Z'(s) = sA'^2(s)$.

It should be noted that to get this expression the Dyson–Schwinger equation (2) has been used again. The UV divergence of Eq. (16) can be illustrated by a simple analytical confining model $g^2 D(p - q) = \frac{3}{16} (2\pi)^4 \eta^2 \delta^4(p - q)$, which was proposed by Munczek and Nemirovsky [20]. In this model, the expression for (16) takes a relative simple form

$$\begin{aligned}
& \frac{1}{6} \int d^4x \langle V | T \left[\bar{q}(x) g_c \frac{\lambda^a}{2} G_{\mu\nu}^a q(x), \bar{q} \sigma_{\mu\nu} q \right] | V \rangle^N \\
& = \frac{1}{16\pi^2} \int ds s \left[\frac{B(s)}{Z(s)} \right]^2 \left[\frac{27}{8} B^2(s) + \frac{27}{2} s A(s) (2 - A(s)) \right] \\
& - \frac{36\eta^2}{16\pi^2} \int ds s Z^{-3}(s) [B^4(s) + sB^2(s)A(s)] + \frac{36\eta^2}{16\pi^2} \int ds s^3 Z^{-3}(s) [A(s) - 1] A^3(s). \tag{18}
\end{aligned}$$

The Nambu–Goldstone solution for this model is

$$A(p^2) = \begin{cases} 2, & p^2 < \eta^2/4, \\ \frac{1}{2} (1 + \sqrt{1 + 2\eta^2/p^2}), & \text{otherwise,} \end{cases} \tag{19}$$

$$B(p^2) = \begin{cases} \sqrt{\eta^2 - 4p^2}, & p^2 < \eta^2/4, \\ 0, & \text{otherwise.} \end{cases} \tag{20}$$

The alternative Wigner solution takes the form

$$B'(p^2) \equiv 0, \quad A'(p^2) = \frac{1}{2} \left(1 + \sqrt{1 + \frac{2\eta^2}{p^2}} \right). \quad (21)$$

Due to $A(s) - 1 \sim c/s$ for $s \rightarrow \infty$ according to (19), the last term of right-hand side of Eq. (18) is logarithmic divergent. In addition, replacing $A(s)$ with $A'(s)$ to (18), there still exists logarithmic divergence due to $A'(s)$ having the same behavior as $A(s)$ in the large energy region. Because the vector part $A(s)$ as well as the scalar part $B(s)$ both reflect the nonperturbative information in the low energy region, it is more reasonable to subtract the corresponding perturbative part rather than to simply ignore this divergent term in (18).

With the effective subtraction of the perturbative contribution, there is no UV divergence in above integrations. Actually, the subtraction procedure guarantees $\kappa \langle \bar{q}q \rangle$ playing the role of the order parameter for QCD chiral phase transition because it becomes zero when QCD undergoes a phase transition from the Nambu–Goldstone phase to Wigner phase (that means $A(p^2) \rightarrow A'(p^2)$ and $B(p^2) \rightarrow 0$).

4. Results and discussions

The determination of the mixed tensor susceptibility is based on the same effective gluon propagator models $g^2 D(s)$, which had been used in Refs. [12,21]. In general, the quark–quark interaction $g^2 D(s)$ has the form

$$g^2 D(s) = \frac{4\pi\alpha(s)}{s}, \quad (22)$$

where $s = p^2$. Two popular quark–quark interaction models with two parameters for $\alpha(s)$ are investigated here:

$$\alpha_1(s) = 3\pi s \chi^2 \frac{e^{-s/\Delta}}{4\Delta^2}, \quad (23)$$

$$\alpha_2(s) = d\pi s \frac{\chi^2}{s^2 + \Delta}, \quad (24)$$

where $d = \frac{27}{12}$. The two low-momentum parameters, the strength parameter χ and the range parameter Δ , are varied with the pion decay constant fixed at 87 MeV which is more appropriate in the chiral limit rather than the pion's mass-shell value of 93 MeV. Noted that the above quark–quark interactions dominate for small s and simulate the infrared enhancement and confinement. Because the effective quark–quark interactions (23), (24) have a finite range in momentum space, the momentum integral for the calculation of the quark condensate

$$\langle \bar{q}q \rangle = -\frac{3}{4\pi^2} \int_0^\infty ds s \frac{B(s)}{sA^2(s) + B^2(s)}, \quad (25)$$

is finite. According to [12], the obtained values of the chiral low energy coefficients L_i following Ref. [21] based on both ansatz (23) and (24) are compatible with the phenomenological values. The model ansatz (24) has been successfully used to investigate the space structure of the non-local quark condensate $\langle \bar{q}(x)q(0) \rangle$ in Ref. [22] within GCM formalism. It should be stressed in this context that our interactions are not renormalizable due to using the bare quark–gluon vertex within the rainbow-ladder truncated DSE formalism. Therefore, the scale at which a condensate is defined in our calculation is a typical hadronic scale, which is implicitly determined by the model quark–quark interaction and the solutions of the DSEs for the dressed quark propagator. The similar case is the determination of the vacuum condensate in the instanton liquid model [24] where the scale is set by the inverse instanton size.

Table 1

The value of $\kappa\langle\bar{q}q\rangle$ for Munczek–Nemirovsky model

η (GeV ²)	$\langle\bar{q}q\rangle^{1/3}$ (MeV)	$\langle\bar{q}\sigma Gq\rangle^{1/5}$ (MeV)	$\kappa\langle\bar{q}q\rangle$ (GeV ⁴)	κ (GeV)

1×10^{-6}	0.77	−204	-2.8×10^{-3}	0.33

To check the sensitivity of the mixed tensor susceptibility on the forms of quark–quark interactions, the above models with different sets of parameters χ and Δ are investigated below, where the results for the quark condensate are also given. For Munczek–Nemirovsky model and the Gaussian type model, the values for the mixed quark–gluon condensate $\langle\bar{q}\sigma Gq\rangle$ are listed in Tables 1–3.

The results for several condensates of QCD vacuum obtained using Munczek–Nemirovsky model are shown in Table 1. This simple confining model has been extensively used by Roberts and his coworkers [25] and the Gaussian type model was inspired by this model. From Table 1 we can see that the mixed tensor susceptibility $\kappa\langle\bar{q}q\rangle$ is very small. In Table 2 we display the values for $\langle\bar{q}q\rangle$ and $\kappa\langle\bar{q}q\rangle$ based on model 1 with three sets of parameters and in Table 3 the same quantities with four sets of parameters based on model 2. In both cases, the obtained values for $\langle\bar{q}q\rangle$ are compatible with the standard phenomenological values in SVZ sum rules, whereas the mixed tensor susceptibility $\kappa\langle\bar{q}q\rangle$ is very small. The previous estimation of $\kappa\langle\bar{q}q\rangle$ obtained in Ref. [6] has opposite sign and its value is 0.10 GeV^4 . Actually, the value of the quark condensate tensor susceptibility $\chi\langle\bar{q}q\rangle$ obtained within GCM formalism [11] is also very small compared with the estimation based on SVZ sum rules. In fact, different versions of SVZ sum rules have given very different values for $\chi\langle\bar{q}q\rangle$ in previous studies [6,8,9]. It shows that the induced vacuum condensates have very little impact on the determination of the nucleon tensor charge from the theoretical formalism of DSEs.

In summary, we have investigated the mixed tensor susceptibility at the mean field level in the framework of GCM/DSE formalism. In the calculations, the vacuum matrix elements for the operator in terms of gluonic fields can be obtained by substituting the gluonic fields with the quark color current operator and the model gluon propagator which describes the effective quark–quark interaction within the GCM formalism. To subtract the perturbative contribution to the expression for the mixed tensor susceptibility, the Wigner solution to the quark gap equation was used self-consistently in this formalism. Using different effective quark–quark interaction models, we find that the mixed tensor susceptibility as well as the quark condensate tensor susceptibility are both very small and the obtained values for these induced vacuum condensates of QCD are not sensitive to the detailed infrared form of $g^2 D(s)$. It shows that the induced vacuum condensates have little effect on the determination of the nucleon

tensor charge from our study. Finally, we want to stress that above approach can also be used to investigate the other mixed susceptibility of the QCD vacuum.
