(which is the largest model available) was still too small for the patient. In all 7 patients, paravalvular leak grade I or greater was found.

CONCLUSIONS

In 10 of 15 patients with postoperative AI or AVB, the new system would have promoted a different valve selection. These observations suggest that the template-based planning approach is a viable aid in preoperative assessment of the atrioventricular geometry and valve selection. To substantiate the reported findings, larger studies are necessary.

Anterior arch translocation for coarctation of circumflex aorta using median sternotomy without cardiopulmonary bypass

Krishnan Ganapathy Subramaniam, MCh, Kulasekharan Marimuthu, MCh, Krishna Manohar, MCh, Sudeep Verma, MD, and Kotturathu Mammen Cherian, FRACS, Chennai, India

The operative approach to the management of coarctation in the presence of hypoplastic circumflex, retroesophageal aorta is not well defined.1-3 We present the case of 4-year-old boy who had coarctation with hypoplastic retroesophageal arch. This was managed by translocation of hypoplastic retroesophageal arch anteriorly and creation of a left neoaortic arch. This was managed by translocation of hypoplastic retroesophageal arch anteriorly and creation of a left neoaortic arch through a median sternotomy without the use of cardiopulmonary bypass. We believe that median sternotomy is the approach of choice in the management of coarctation of the circumflex aorta.

CLINICAL SUMMARY

A 4-year-old boy weighing 14 kg had dyspnea on exertion and palpitations with increased precordial activity gradually worsening over the prior 2 years. On diagnostic workup, which included echocardiography, cardiac catheterization, and magnetic resonance angiography, he was found to have a circumflex aorta with coarctation and hypoplasia of the retroesophageal portion of the arch. The origin of the left subclavian artery (LSCA) was stenotic. The vessels of the ascending aorta were the left common carotid artery, the right common carotid artery, and the right subclavian artery. A coarctation was present at the base of right subclavian artery, with hypoplasia of the retroesophageal portion. A Kommerell diverticulum was present at the proximal portion of the descending aorta, which gave rise to a stenotic LSCA and a long narrow ductus. Although there was a complete vascular ring, the relatively long ductus probably did not cause any symptoms of tracheoesophageal compression (Figure 1).

We decided to approach the repair through a sternotomy. After median sternotomy and complete thymectomy, the ascending aorta, all 4 arch vessels, the patent ductus arteriosus, and the descending aorta were dissected. The descending aorta was extensively mobilized to the level of the first intercostals to achieve a tension-free anastomosis. The arch of the aorta to the right and left of the esophagus was looped as well. The patient was heparinized. The arch of the aorta at the base of right subclavian artery was transfixed and divided. The arch was mobilized from behind the esophagus. There were no vessels arising from this part of the aorta to the esophagus. The patent ductus was divided and the base of the stenotic LSCA was divided and transfixed as well. The arch was translocated anteriorly after division of the LSCA and ductus. A side-biting clamp was applied to the ascending aorta at the base of left carotid artery. After spatulation of the arch, it was anastomosed to the side of

ascending aorta with 6–0 polypropylene. The base of the Kommerell diverticulum was clipped with a large Ligaclip ligating clip (Ethicon, Inc, Somerville, NJ), excluding the diverticulum (Figure 2). There was no gradient between the right radial artery and the femoral artery. The clamp time was 21 minutes. The patient was extubated on the second postoperative day and was discharged home on the seventh day with no residual gradient.

DISCUSSION

The main issue in the management of the patient was the approach to repair the coarctation and hypoplastic arch in a circumflex aorta. On literature review, 2 approaches have been described. One was mobilization and end-to-end anastomosis in an infant with ventricular septal defect on cardiopulmonary bypass. The second approach was to use an extra-anatomic conduit between the ascending and descending aorta using a right thoracotomy approach. Our patient differed from these cases in that we were not certain that he was young enough to permit extensive mobilization in the absence of any intracardiac anomaly that did not necessitate the use of cardiopulmonary bypass. We did not think that he was old enough to warrant an extracardiac conduit. We thought achieving native tissue–tissue anastomosis was preferable and we opted for a sternotomy approach, which would also permit easy institution of cardiopulmonary bypass if necessary.

Median sternotomy allowed extensive mobilization of the arch and arch vessels on either side of the esophagus. A noncompressive vascular ring, which was formed by

Successful thoracoscopic surgery for intractable pneumothorax after pneumonectomy under local and epidural anesthesia

Masafumi Noda, MD, Yoshinori Okada, MD, Sumiko Maeda, MD, and Takashi Kondo, MD, Sendai, Japan

Management of pneumothorax in patients with limited pulmonary function of the contralateral lung is complicated. Among these situations, pneumothorax after pneumonectomy is potentially lethal and its treatment poses a significant risk. We report a case of intractable right pneumothorax after left pneumonectomy, successfully treated by video-assisted thoracic surgery (VATS) under local and epidural anesthesia.

CLINICAL SUMMARY
A 74-year-old male patient underwent left pneumonectomy and mediastinal lymph node dissection for squamous cell carcinoma of the left upper lobe. After surgery, he developed an intractable right pneumothorax, which was treated with video-assisted thoracic surgery (VATS) using local and epidural anesthesia. The surgical approach was facilitated by the use of a large Ligaclip ligating clip at its base. The division of the subclavian artery would prevent a slingshake effect, which would predispose to tracheoesophageal compression.

In summary, we believe that median sternotomy is the best approach in the management of coarctation of the circumflex aorta. It permits extensive mobilization of the arch and arch vessels on either side of the esophagus. The mobilized arch can easily be translocated anteriorly to achieve native tissue-tissue anastomosis. It also allows management of vascular ring and Kommerell diverticulum. The presence of a vascular ring may be difficult to diagnose in the absence of symptoms, and it has the potential to cause late-onset symptoms of predominantly esophageal compression. This approach also permits correction of any additional intracardiac defect.
