**Corresponding author:** Tel.: +886 7 7317123x8304; fax: +886 7 7322402. E-mail address: 88b0@adm.cgmh.org.tw (J.-W. Liu).

**KEYWORDS**

*Shewanella*; *Shewanella algae*; Soft tissue infection; Necrotizing fasciitis

**Summary**

**Objective:** To better understand the clinical characteristics of soft tissue infections caused by *Shewanella* in humans.

**Methods:** We report a case of *Shewanella* soft tissue infection and review the English literature from a search of PubMed.

**Results:** A total of 27 adults (mean age 61.1 ± 16.0 years) with soft tissue infections caused by *Shewanella* were included for analysis. Limb involvement was found in 22 (81.5%) patients, while scalp, face, perineum, lacrimal sac, and abdominal wall involvement were each found in one patient. Chronic ulcer over the leg (14 cases (51.9%)), steroid use (four cases (14.8%)), and liver cirrhosis (three cases (11.1%)) were the major underlying conditions. *Shewanella* bacteremia was found in 14 out of 22 patients with soft tissue infections involving the limbs. Two patients died of septicemia, giving a mortality rate of 7.4%.

**Conclusions:** *Shewanella* soft tissue infections usually develop in immunocompromised patients with a preexisting cutaneous ulcer (particularly over the legs) after marine environment or seawater exposure. In view of the possible catastrophic consequences, education on the prevention of *Shewanella* soft tissue infections in at-risk people (e.g., the immunocompromised or elderly with a cutaneous ulcer) relating the need to avoid exposure to the marine environment or seawater may be of importance.

**Introduction**

*Shewanella* spp are motile Gram-negative bacilli with the major phenotypic characteristic of production of large...
amounts of hydrogen sulfide (H$_2$S) in the butt of triple sugar iron agar. Shewanella alga and Shewanella putrefaciens are frequently found in non-human sources such as the marine environment and foodstuffs, yet are opportunistically pathogenic for humans. S. putrefaciens was once believed to be the major human pathogenic species in the genus Shewanella, and authors in most of the earlier reports on Shewanella human infections attributed the etiology to S. putrefaciens. The taxon S. alga was previously considered one biogroup of the genetically heterogeneous S. putrefaciens species. In 1990, S. alga was first recovered from red algae and was proposed to be a tetrodotoxin-producing microbe. A subsequent study disclosed that the high G+C content in the previously recognized S. putrefaciens isolates were genetically related to S. alga, and most of the clinical S. putrefaciens isolates should therefore be reclassified as S. alga. In 1997, S. alga was renamed S. alga. It is likely that >80% of clinical Shewanella isolates in human infections are S. alga.

Although S. alga was recognized as a new species in 1992, misidentification of S. alga as S. putrefaciens has persisted ever since. These misidentifications have resulted from the failure of both conventional phenotypic characteristic testing and commercialized bacterial identification systems (e.g., ID 32 GN, and VITEK) in differentiating S. putrefaciens from S. alga. In humans, soft tissue infections are mostly encountered among infections reported to be caused by Shewanella species. To better understand clinical characteristics of soft tissue infections caused by Shewanella in humans, we report a case of severe soft tissue infection caused by S. alga in an immunocompromised adult and review the literature.

Case report

A 42-year-old man with an underlying hepatitis B-related liver cirrhosis was hospitalized because of fever and a swollen left leg. He had injured his left leg 2 days earlier when he was handling a seawater fish in preparation for his dinner. Some skin lesions developed when his leg was stuck by the spinous dorsal fin of the fish, and he tried to clean the oozing blood from the damaged skin by flushing it with the water in which the fish had been immersed before. Local heat and swelling over his left leg soon developed, followed by fever and rigors. Upon admission, he was acutely ill; his body temperature was 39.8°C, and blood pressure was 90/60 mmHg. Physical examination revealed an extremely swollen left leg with edematous dark red to purple-colored skin, and some hemorrhagic bullae on the soft tissue over the distal end of the left leg and the left ankle joint.

Blood tests revealed that his peripheral leukocyte count was $2.7 \times 10^9$/l (normal 3.9–10.6 $\times 10^9$/l) with the presence of band-form cells and metamyelocytes, and his platelet count was $37 \times 10^9$/l (normal 150–400 $\times 10^9$/l). C-reactive protein was 70.1 mg/l (normal <5 mg/l), aspartate aminotransferase was 146 (normal <37 U/l), alanine aminotransferase was 55 U/l (normal <40 U/l), and serum creatinine was 1.8 mg/dl (normal 0.4–1.4 mg/dl). A computed tomography revealed severe edematous changes of the subcutaneous tissue and muscles in the left leg. Under the impression of necrotizing fasciitis and septic shock, parenteral ceftriaxone (2 g/day) and oral doxycycline (200 mg/day) were empirically administered after sampling blood for culture, and an emergency operation was performed. The surgical procedure included fasciotomy and extensive debridement of the devitalized soft tissue along the lateral side of the tibialis anterior of the affected leg, from the level below the knee joint to the ankle joint. The excised devitalized soft tissue disclosed supplicative necrosis on histopathology. The administered antibiotics were switched to ciprofloxacin (1200 mg/day parenterally).

Although it was hemodynamically stable after surgery, his left leg did not make a favorable clinical response. The non-excised skin and muscles around the surgical site of his left leg were poorly perfused. On day 4 of hospitalization, cultures of blood and excised necrotic tissue sampled during the operation both yielded Gram-negative rods, which were identified as S. putrefaciens by ID 32 GN (bioMérieux Vitek, Inc., Hazelwood, MO, USA). Susceptibility testing using VITEK 1 automated system (bioMérieux Vitek, Inc.) indicated that the isolated microbe was susceptible to aztreonam, ampicillin/sulbactam, piperacillin/tazobactam, ceftazidime, ceftriaxone, ciprofloxacin, levofloxacin, imipenem, gentamicin, and amikacin. To definitively identify the isolated pathogen, the partial 16S rRNA gene was sequenced by PCR amplification using a universal forward primer 27F (5'-AGAGTTTGATCCTGGCTCAG-3') and a universal reverse primer 907R (5'-CGCTACATGTTT-GAGTT-3'), as previously described. Two harvested DNA isolates (each with 881 and 895 nucleotides) were sequenced by 310 Genetic Analyzer (Applied Biosystems) and were compared with those available in the GenBank database (http://www.ncbi.nlm.nih.gov/BLAST/BLAST.cgi); they were found to be a 100% match with those of S. alga.

With regards to susceptibility, Etest on this S. alga isolate was performed in accordance with the instructions of the manufacturer (AB Biodisk, Solna, Sweden). The selected antimicrobials (minimum inhibitory concentrations (MICs) in μg/ml) were as follows: cephalothin (>256), cefotaxime (0.19), ceftriaxone (0.25), ceftazidime (0.25), cefepime (0.047), ciprofloxacin (0.19), levofloxacin (0.25), ampicillin/sulbactam (0.75), piperacillin/tazobactam (0.125), ertapenem (0.38), imipenem (6), and meropenem (0.38). Ciprofloxacin was continued because of its favorable MIC.

In spite of antimicrobial use, progressive clinical deterioration was observed. The patient received two further debridement procedures in the affected leg, and as a result, a considerable portion of skin and muscles in his left leg was excised. All the excised tissues were suppuratively necrotic by histopathology. Because of persistent deterioration, his left leg was amputated from the level of above-knee joint on hospitalization day 16. Thereafter his course was uneventful, and the patient was discharged on day 31.

PubMed search and literature review

We performed a PubMed search for reports on Shewanella infections that have been published since 1966 using the keywords ‘Shewanella alga’, ‘Shewanella alga’, ‘Shewanella putrefaciens’ and ‘Pseudomonas putrefaciens’ (the previous name for Shewanella putrefaciens), and limited the search to the English literature and adult humans. A total of 27 adults (mean age 61.1 ± 16.0 years) with soft tissue infections caused by S. alga, S. alga, S. putrefaciens or P. putrefaciens were found. Demographic, clinical, and

M, male; F, female; CoNS, coagulase-negative staphylococci; COPD, chronic obstructive pulmonary disease; SLE, systemic lupus erythematosus; NA, not available.
All patients survived except for patient cases 5 and 19 who died of sepsis and patient case 18 who died of underlying diseases.

* Pseudomonas putrefaciens is the previous name for *Shewanella putrefaciens* and *Shewanella alga* is the previous name for *Shewanella alga*.

a Case No. 1 was separately reported in two different articles.

b ID 32 GN, API 20E, API ZONE, VITEK, VITEK II, API Rapid NFT system, GNI, and BBL Crystal are commercial devices, which were used manually, semi-automatically, or automatically for the identification of bacteria.
laboratory information for these patients are summarized in Table 1.

Of the 27 patients with soft tissue infections, limb involvement (18 lower and four upper limbs) was found in 22 (81.5%), while scalp, face, perineum, lacrimal sac, and abdominal wall involvement were each found in one patient. With regard to the leading underlying diseases/conditions, chronic ulcer over the leg (14 cases (51.9%)) resulting from a variety of causes including venous stasis, arterial insufficiency, diabetic foot, chronic leg edema, or traumatic wounds was most commonly found, followed by steroid use (four cases (14.8%)) and liver cirrhosis (three cases (11.1%)). Shewanella bacteraemia was found in 14 of the 22 patients with soft tissue infections involving the limbs (11 cases of monomicrobial bacteraemia and three of polymicrobial bacteraemia), and in one of the five cases of soft tissue infection involving other anatomic sites. Overall, two patients died of septicemia, giving a mortality rate of 7.4%.

Discussion

Out of more than 30 already known Shewanella species, only S. putrefaciens and S. algae are considered pathogenic for humans. The reason why S. algae causes more infections in humans than S. putrefaciens is not fully understood. Some investigators have hypothesized that the bacterial hemolysin produced by the culprit S. algae plays an important role in the pathogenesis of human infection.17

Remarkably, in addition to a variety of immunocompromising conditions, a preexisting chronic ulcer over the lower limb was found in more than 50% of the affected patients. Because Shewanella species normally exist in the marine environment, the cutaneous breaches on the legs of these immunocompromised patients served as a portal of entry for the opportunistic pathogens during their recreational activities.

Unlike the previously reported cases of Shewanella soft tissue infections, our case was clinically fulminant and resembled the rapidly progressive soft tissue infections caused by Vibrio vulnificus24-28 and Aeromonas species,29 which are characterized by the emergence of bullae and rapid development of progressive necrotizing fasciitis and septic shock. The clinical manifestations of this case suggest that when it comes to the etiology for a severe soft tissue infection, S. algae, V. vulnificus, and Aeromonas spp should all be included in the differential diagnosis. The possibility that the initial debridement was inadequate in our patient cannot be excluded in view of the fact that deterioration subsequently developed rapidly under prompt and aggressive surgery in combination with effective antibiotics.

Earlier studies have demonstrated that aminoglycosides, levofloxacin, third- and fourth-generation cephalosporins, piperacillin, and carbapenems are active in vitro against S. putrefaciens.30,31 The antimicrobial susceptibilities of our clinical isolate were similar to those described previously.25,31 Of note, imipenem had a higher MIC against the clinical Shewanella isolates than meropenem, as has been shown in other reports.30,31 In terms of antimicrobial susceptibility, some Shewanella isolates are intrinsically resistant to imipenem,31 while some that were originally susceptible to imipenem may develop resistance to this antibiotic after clinical exposure to it.32 A chromosome-encoded carbapenem-hydrolyzing Amber class D β-lactamase harbored by the microbes has been reported to be responsible for the high MIC of imipenem against S. algae isolates.31 Further study is warranted to clarify the role of empirical treatment with a carbapenem in soft tissue infections in patients with marine exposure.

Given the possible catastrophic consequences, education on the prevention of Shewanella soft tissue infections in at-risk people (e.g., the immunocompromised or elderly with a cutaneous ulcer) relating the need to avoid exposure to the marine environment or seawater may be of importance.
