The State of Endovenous Ablation for Venous Insufficiency in Florida

Background: Endovenous ablation has recently been adopted for treatment of lower extremity venous insufficiency. We sought to define the current trends in the use of endovenous procedures and the impact on the associated costs in the state of Florida (Fig).

Methods: The Agency for Healthcare Administration database, which contains 100% of encounters from ambulatory centers in Florida, was queried for endovenous laser or radiofrequency ablation procedures, using Current Procedural Technology codes 36478 and 36475, respectively, for the study period of Q1 of 2005 to Q3 of 2008. International Classification of Diseases-9 diagnostic codes were used to identify severity of the venous disease. The main measures included type of ablation, provider specialty, and total charges. A comparison of practice patterns and associated charges were performed for the two main provider groups, namely general/vascular surgeons (GS/VS) and diagnostic/interventional radiologists (DR/IR).

Results: Our query consisted of 4,143 encounters during the study period. The mean age was 54 ± 13 years, and 73% were women. Compared with the Florida population, white and white-Hispanic race was over-represented (91.4% vs Florida 81%), and black race was under-represented (9.1% vs Florida 16%). The most common complaint was asymptomatic venous insufficiency (12.6%), unspecified venous insufficiency (11.9%), and phlebitis/thrombophlebitis (10.2%). Laser ablation outnumbered radiofrequency ablation each year (mean 697 vs 503). In total, 21 specialties were represented. Other providers of note include cardiothoracic surgeons (1.2%) and DR/IR (3.8%). In total, 21 specialties were represented. Other providers of note include cardiothoracic surgeons (1.2%) and DR/IR (3.8%). In total, 21 specialties were represented.

Conclusions: Endovenous ablation offers a minimally invasive option for treatment of venous insufficiency. Although providers span a wide range of specialties, the majority of endovenous ablations performed in ambulatory centers are performed by general or vascular surgeons. GS/VS performed substantially more secondary procedures compared with DR/IR, resulting in higher total charges. More studies are required to determine whether this disparity in practice patterns result in different outcomes.

Randomized Controlled Trial of Ultrasonic Guided Foam Sclerotherapy Combined with Sapheno-Femoral Ligation Compared to Surgical Treatment of Varicose Veins: Five-year Results

E. Kalodiki, A. Azzam, C. R. Latimer, E. Shawish, N. Zambas, and G. Geroulakos, The Ealing Hospital and Imperial College London, London, United Kingdom; and the Ealing Hospital, Middlesex, United Kingdom.

Background: Up to 5-year results of a prospecively randomized controlled trial comparing foam sclerotherapy and surgery to standard surgery, in patients with primary varicose veins.

Methods: Seventy-three patients (82 legs) underwent sapheno-femoral ligation, stripping, and multiple phlebectomies under local anesthesia (n = 43; M/F, 16:23; mean age, 47 years [range, 23-76 years]; group S) or sapheno-femoral ligation under local anesthesia and concurrent sclerotherapy (n = 43; M/F, 11:32; mean age, 49 years [range, 26-42 years]; group F). Assessments included CEAP classification, ultrasound, Venous Clinical Severity Score (VCSS), Aberdeen Varicose Vein Questionnaire (AVVQ), and Short Form 36 (SF36) scores.

Results: CEA was similar between groups, C2-6. On the 59 legs with completed ultrasound, reflux at 3 to 5 years is presented (Table I).

In group S, 40% of legs required 25 additional foam sessions with a mean volume of 11 mL and a total volume of 154 mL. In group F, 47.5% of legs required 33 additional sessions with a mean volume of 9 mL and a total volume of 207 mL. Preoperatively the VCSS score was equivalent between the two groups (median-range-Interquartile Range [IQR]; group S: 5, 3-12, 3 and group F: 4.5, 2-15, 2; P = .389 Mann-Whitney U test). However, after treatment there was improvement within both groups (median-range-IQR for group S: 1, 0-9, 5; P = .003; and group F: 1, 0-9, 2; P < .0005 Wilcoxon). Changes in VCSS before and at 3 years (P = .504) and the absolute VCSS scores (P = .388) were similar between both groups. The Venous Disease Severity Score (VSDS) score improved in both groups due to treatment (Table II).

The AVVQ score also improved within both groups (median-interquartile range preoperatively vs 3 years [S: 16.32-4.7 vs 8.94-11.51; P = .194; F: 12.28-10.37 vs 4.97-6.19; P = .780]). The improvement on the AVVQ score before and after treatment was similar compared with the Florida population, white and white-Hispanic race

A New Approach to the Genetics of Varicose Veins: A Genome-wide Association Study

A. M. van Rij, J. Krysa, and G. T. Jones, The University of Otago, Dunedin, New Zealand

Background: The exact nature of the genetic basis of varicose veins remains unclear. A number of genetic associations have been described. These have, however, all been relatively small, limited-candidate gene studies, none of which have been validated. The aim of this study was to consider these current reported genetic associations with varicose veins and to carry out a case control analysis to validate them, using the approach of a more comprehensive unbiased genome-wide association study (GWAS).

Methods: An indirect, in silico, GWAS of varicose veins was undertaken. This was based on our abdominal aortic aneurysm GWAS in which the frequency of varicose veins was similar in cases and controls. Genetic polymorphisms associations with venous disease to date were identified through a literature search. All known single nucleotide polymorphisms, with >5% allele frequency in the genes previously implicated, were analyzed. Genotyping was carried out using Affymetrix genome-wide human single nucleotide polymorphisms array 6.0.

Results: Three hundred forty-nine patients with varicose veins and 857 controls were included. Genes which have been implicated in venous disease so far include FOXC2, HEF C282T, factor XIII V34L, estrogen receptor B, TNF-A, MTHFR, and thrombomodulin. None of the single-nucleotide polymorphisms in these genes have shown to have significant association in this study. However, there were a number of other single-nucleotide polymorphisms that were found to be associated with varicose veins. Some of these are quite novel and previously not linked to venous disease. These are being further validated in another larger and more strictly phenotyped cohort.

Conclusions: This is the first GWAS applied to varicose veins. The previous candidate genes implicated in common venous disease have not been confirmed. A GWAS approach has been shown to be useful in validation and discovery of novel genes in venous disease. Further larger cohorts are required to confirm these.

Thrombolytic Therapy with Tissue Plasminogen Activator: Why Protracted Continuous Infusion is not the Best Approach

Background: Continuous infusion has been assumed to be the optimal way of administering every thrombolytic agent approved for clinical use. However, this simplistic approach fails to take advantage of differences in properties of thrombolytic agents that could be exploited to increase efficacy as well as safety. In particular, continuous infusion is not necessary when using thrombolytic agents with strong fibrin binding and is not the optimal way of administering recombinant tissue plasminogen activator (r-tPA or alteplase). Once given by intracal injection, alteplase binds to fibrin clot, and once bound to clot, its activity as a plasminogen activator increases with time. The fibrin clot is also replaced by tPA, prolonged fibroinolysis ensues, obviating the need for protracted infusion.

Methods: Forty-five patients with subclavian, jugular, or central venous thrombosis (SJ-CVT) and 56 patients with acute deep vein thrombosis of the lower extremity (DVT-LE) were treated with once daily intracal injection of tPA without prolonged infusions of tPA, but with a short half-life (T1/2 = 2 min). The thrombotic load was most parallel to the serial injection approach that reached the systemic circulation during injection is cleared rapidly due to its short half-life (T1/2 = 2 min) shortening the duration of the systemic levels and suppressed plasminogen activator inhibitor levels are persistent as long as the prolonged infusion continues.

Postoperative Deep Vein Thrombosis in Total Knee or Hip Replacement Operation is Associated with Preoperative Increased Calf Muscle Deoxygenation

T. Yamaki, A. Hamahata, D. Fujisawa, H. Konoeda, K. Kubo, M. Nozaki, and H. Sakurai, The Tokyo Women's Medical University, Tokyo, Japan

Background: To assess whether preoperative calf muscle deoxygenated hemoglobin (HHb) level during light-intensity exercise is useful for identifying patients at risk of developing postoperative deep vein thrombosis (DVT).

Methods: Sixty-three patients receiving either total knee or total hip replacement operation were enrolled. Preoperative screening using compression ultrasound of the bilateral calf veins was done. None of the patients already had deep vein thrombosis. The mean flow velocity of the popliteal vein (POPV) was assessed. Moreover, prevalence of venous reflux in the POPV was evaluated preoperatively. Near-infrared spectroscopy was used to measure calf muscle HHb levels. Calf venous blood filling index (HHbFI) was calculated on standing, then the calf venous ejection index (HHeI) was obtained after one tiptoe movement and the venous retention index (HHReI) after ten tiptoe movements. All patients received fondaparinux for postoperative thromboprophylaxis.

Results: There were no preoperative DVT. Of 63 patients evaluated, postoperative compression ultrasound confirmed DVT in 13 (20.6%) patients. There were no significant differences in mean age, body mass index, and gender distributions between patients with postoperative DVT and those without. There was no significant difference in the mean flow velocity in the POPV between patients with postoperative DVT and those without. HHbFI was significantly increased in patients who developed deep vein thrombosis in comparison with those who did not (7.78 ± 8.65, 1.83 ± 2.30, P = 0.062). Reflux in the POPV was found in three patients with postoperative DVT and 12 without postoperative DVT, and there was no significant difference between the groups (P = 0.945). The postoperative near-infrared spectroscopy-derived HHReI was significantly increased in patients who developed deep vein thrombosis in comparison with those who did not (7.78 ± 8.65, 1.83 ± 2.30, P = 0.006, respectively). There were no significant differences in the values of HHbFI and HHeI between the study groups.

Conclusions: These results suggest that HHReI, as measured by near-infrared spectroscopy, may be a promising parameter for identifying patients at risk of developing postoperative DVT despite pharmacologic deep vein thrombosis prophylaxis. These findings might be very helpful for physician in detecting patients who require more extensive thromboprophylaxis.

Postoperative Deep Venous Thrombosis in Total Knee or Hip Replacement Operation is Associated with Preoperative Increased Calf Muscle Deoxygenation

Background: Previous studies utilizing national or regional data demonstrated that a significant proportion of deep vein thrombosis (DVT) is diagnosed in the outpatient setting. Little is known, however, about patient characteristics, referral patterns, and percentage of positive DVT in patients referred to outpatient vascular laboratories. The study objective was to examine demographics, risk factors, presenting symptoms, and referring physician specialties in patients referred to outpatient vascular laboratories (OVL) and to delineate clot extent in patients diagnosed with DVT.

Methods: Data was retrospectively collected from an OVL database of 1506 patients referred to rule out DVT over a 13-month period. Data collected included patient age, gender, risk factors, presenting symptom(s), and referring physician specialty. Patients were categorized (acute or chronic), and extent of DVT was classified on a scale of 1 to 4 (4 = gastronemius vein, 3 = tibial vein, 2 = femoral and/or popliteal vein, and 1 = common femoral and/or popliteal veins). Logistic regression was used to quantify association of risk factors with the presence of acute DVT.
