Relaxed matrix vector-product

#### Abstract

The inexact GMRES algorithm is a variant of the GMRES algorithm where matrix-vector products are performed inexactly, either out of necessity or deliberately, as part of a trading of accuracy for speed. Recent studies have shown that relaxing matrix-vector products in this way can be justified theoretically and experimentally. Research, so far, has focused on decreasing the workload per iteration without significantly affecting the accuracy. But relaxing the accuracy per iteration is liable to increase the number of iterations, thereby increasing the overall runtime, which could potentially end up being greater than that of the exact GMRES if there were not enough savings in the matrix-vector products. In this paper, we assess the benefit of the inexact approach in terms of actual CPU time derived from realistic problems, and we provide cases that provide instructive insights into results affected by the build-up of the inexactness. Such information is of vital importance to practitioners who need to decide whether switching their workflow to the inexact approach is worth the effort and the risk that might come with it. Our assessment is drawn from extensive numerical experiments that gauge the effectiveness of the inexact scheme and its suitability for use in addressing certain problems, depending on how much inexactness is allowed in the matrix-vector products.

## 1. Introduction

The generalized minimum residual (GMRES) method of Saad and Schultz [1] is a popular technique for solving nonsymmetric linear systems of the form

$$
\begin{equation*}
A x=b \tag{1}
\end{equation*}
$$

where $A$ is a nonsingular, large sparse matrix of dimension $n$, often with irregular structure. Given an initial estimate $x_{0}$ with corresponding residual vector $r_{0}=b-A x_{0}$, GMRES uses the Arnoldi process to build an orthogonal basis of the Krylov subspace

$$
\mathcal{K}_{m}=\operatorname{Span}\left\{r_{0}, A r_{0}, A^{2} r_{0}, \ldots, A^{m-1} r_{0}\right\}
$$

The Arnoldi process leads to a relationship of the form

$$
\begin{equation*}
A V_{m}=V_{m+1} \bar{H}_{m}=V_{m} H_{m}+h_{m+1, m} v_{m+1} e_{m}^{T} \tag{2}
\end{equation*}
$$

where $V_{m}=\left[v_{1}, v_{2}, \ldots, v_{m}\right]$ is a basis of $\mathcal{K}_{m}$ and $H_{m}=V_{m}^{T} A V_{m}$ is upper Hessenberg, while $\bar{H}_{m}$ is $H_{m}$ augmented with $h_{m+1, m} e_{m}^{T}$ in its last row. Here $e_{m}$ denotes the $m$ th column of the identity matrix $I$ of appropriate size depending on its context. In exact arithmetic, GMRES converges in at most $n$ steps, i.e., if $m=n$. However, because $n$ is large the amount of

[^0]storage and the cost of orthogonalization in the Arnoldi process make it impractical to set $m=n$ and so restarting is used and $m \ll n$ in practice, which is why we will understand GMRES as meaning restarted GMRES unless the distinction is made explicit.

Variants of GMRES have been proposed, including most recently the inexact approach considered in this study. This approach uses approximate matrix-vector products [2,3], and it has been shown to work well even in some regularization applications where the coefficient matrix is singular [4]. To make the difference clear, we will call exact GMRES the classical method and this is not meant to imply exact arithmetic. The general principle of the inexact variant is to perform the matrix-vector product approximately as

$$
A v \approx(A+E) v
$$

where $E$ models some error matrix that varies with each product. Such inexactness (or relaxation) has been motivated by applications where the matrix is not known exactly or it is too expensive to apply. Research, so far, has focused on the modification that will decrease the workload per iteration without significantly affecting the accuracy. But relaxing the accuracy per iteration is liable to increase the number of iterations, thereby increasing the overall execution time, which could potentially end up greater than that of the exact GMRES should there be not enough savings in the matrix-vector products to compensate for the overhead of the extra iterations, if any. A related concern is that implementing a relaxation strategy may come at extra cost too. As we deal with large matrices over possibly thousands of steps, the inherent overhead of a given relaxation strategy may itself build up to a sizable proportion that has to be offset as well.

Our study will investigate the actual CPU time, which is an aspect that has received less attention so far. Such information is of vital importance to practitioners who need to decide whether switching their workflow to the inexact approach is worth the effort and the risk that might come with it. Also, regardless of the savings in computational time, practitioners are concerned about the robustness and reliability of newer solution techniques aimed at replacing what they have been accustomed to. Hence should a method fail to produce accurate enough answers, a trustworthy feedback (e.g., a residual) should be provided. But the difficulty is compounded in the inexact scheme by the so-called residual gap that we will discuss later. To assess all the aspects above with respect to inexact GMRES, we have performed extensive numerical experiments to gauge the effectiveness of the inexact scheme and its suitability for use in addressing certain problems, depending on how much inexactness is allowed in the matrix-vector products.

We developed three implementations to obtain our results:

- An optimized FORTRAN90 code based on SLAP (Sparse Linear Algebra Package [5]), where we focused on adapting the matrix-vector product to be inexact, based on a user-specified tolerance. Details on this will be given later. This represents the typical way that practitioners might proceed in changing their existing workflow. The timings reported throughout this study come from this optimized version.
- A separate instrumentation FORTRAN90 code based on the same SLAP code as above. In this code, we computed and captured all the additional debugging and instrumentation information aimed at allowing us to monitor the inexact solver without skewing the execution times to be reported. It is with this version that we computed the residual gap and the data used in the various tables and plots and reported in this study.
- A MATLAB implementation that we used to check the correctness of our changes to the SLAP code. While not as efficient as the compiled FOTRAN90 codes, it provided a convenient interface for fast prototyping and confirmation of the results reported in this study.
The organization of the paper is as follows. Section 2 summarizes the inexact method including some theoretical results pertaining to the impact of inexact matrix-vector products on the true residual. In Section 3 we describe our strategies for allowing the inexactness to percolate through the computations on the basis of a user-specified tolerance. In Section 4, we conduct a detailed series of experiments on both a desktop PC and a supercomputer as part of our performance analysis, leading in particular to the observation that for small problems ( $n \leq 10,000$ ), the time that it takes to run either variant is very short, making the inexact variant not worth the porting effort in such cases. In Section 5 we provide concluding remarks.

## 2. The inexact GMRES algorithm

It is assumed that the reader is familiar with Krylov subspace techniques, or can consult for example [6,1] for more detailed information and background on the classical GMRES. In recent years there has been an interest in transitioning from exact matrix-vector products to inexact matrix-vector products in GMRES, either out of necessity or deliberately, as part of a trading of accuracy for speed. Results have been quite promising thus far [2,3,7]. Algorithm 1 shows a pseudo-code for the inexact variant in which as we noted earlier the inexact matrix-vector operation is modeled as

$$
w_{k}:=\left(A+E_{k}\right) v_{k} .
$$

If we set $E_{k}=0$ in the algorithm, we recover the classical GMRES. The foremost implication of such a relaxation of the matrix-vector product is that the classical Arnoldi relationship (2) no longer holds. Rather, we now have (in the notation of [7])

$$
\begin{equation*}
\left(A+\mathcal{E}_{m}\right) V_{m}=V_{m+1} \bar{H}_{m}, \quad \mathcal{E}_{m}=\sum_{k=1}^{m} E_{k} v_{k} v_{k}^{T} \tag{3}
\end{equation*}
$$

or alternatively (in the notation of [3])

$$
\begin{equation*}
A V_{m}+F_{m}=V_{m+1} \bar{H}_{m}, \quad F_{m}=\varepsilon_{m} V_{m}=\left[E_{1} v_{1}, \ldots, E_{m} v_{m}\right] \tag{4}
\end{equation*}
$$

where these equalities exploit the noteworthy fact that the basis $V_{m}$ remains orthonormal. As noted in [7], the relation (3) makes it clear that $V_{m}$ is a basis for a subspace spanned by the elements of a Krylov sequence obtained by some perturbation of the matrix $A$, where the perturbation is updated at each step. From theoretical and experimental evidence, the method can withstand cases where the norm of the perturbation $\S_{m}$ grows very large, and in effect the greater the iteration number $k$, the larger the error $E_{k}$ allowable in the matrix-vector product.

## AlGorithm 1: Inexact GMRES

Choose an initial estimate $x_{0}$ and compute $r_{0}:=b-A x_{0}$;
repeat
$\beta:=\left\|r_{0}\right\|_{2} ; \quad v_{1}:=r_{0} / \beta ;$
for $k=1,2, \ldots, m$, do
$w_{k}:=\left(A+E_{k}\right) v_{k} ;$
for $i=1,2, \ldots, k$ do
$h_{i k}:=v_{i}^{T} w_{k} ;$
$w_{k}:=w_{k}-h_{i k} v_{i} ;$
end
$h_{k+1, k}:=\left\|w_{k}\right\|_{2}$;
if $h_{k+1, k} \approx 0$ then
$m:=k$;
break ;
end
$v_{k+1}:=w_{k} / h_{k+1, k} ;$
end
Define the $(m+1) \times m$ Hessenberg matrix $\bar{H}_{m}=\left(h_{i k}\right)_{1 \leq i \leq m+1,1 \leq k \leq m}$;
Solve the least squares problem min $\left\|\beta e_{1}-\bar{H}_{m} y_{m}\right\|_{2}$ for $y_{m}$;
Set $x_{0} \leftarrow x_{m}:=x_{0}+V_{m} y_{m}$ and $r_{0} \leftarrow r_{m}:=b-A x_{m}$;
until convergence ;
Ideally, we look to reduce the number of operations, in order to make the CPU time smaller while keeping the same accuracy. Our numerical results in Section 4 show that provided that the distribution of non-zero elements per column is suitable, our times for the inexact matrix-vector products are less than that for the exact matrix-vector products. However, we observed that a reduced time does not come with the guarantee that the solution is as accurate as claimed by the inexact solver. This is because there is a discrepancy between the true residual that exact GMRES would provide and the estimated residual computed by inexact GMRES. This is the so-called residual gap issue and we shall start by discussing this issue in greater detail, as it is important in practice. Our discussion gives some additional insights into the issue and our experiments include a few instructive cases where the estimated residual of inexact GMRES does not have the very valuable monotonic property that the true residual of exact GMRES has. We shall even see a notorious case later where the computed residual increases dramatically.

### 2.1. The residual gap

Both the exact and inexact GMRES methods (cf. Algorithm 1) use the update formula

$$
x_{m}=x_{0}+V_{m} y_{m},
$$

where $x_{0}$ is the initial guess and $y_{m}$ is obtained by solving the least squares problem

$$
y_{m}=\arg \min _{y}\left\|\beta e_{1}-\bar{H}_{m} y\right\|_{2}, \quad r_{0}=b-A x_{0}, \quad \beta=\left\|r_{0}\right\|_{2}
$$

Associated with the new iterate $x_{m}$ is the true residual

$$
r_{m}=b-A x_{m}
$$

but it is well known that it is not computed in this way in highly optimized production codes-neither by the exact GMRES nor by the inexact variant, where in this latter case, it is better not to assume that the matrix-vector product $A x_{m}$ can be performed exactly at will (although we shall see later that a completely inexact method is hard to achieve). Obtaining meaningful bounds on the true residual under such restrictions in the inexact setting has been analyzed in [7] as we summarize here. Recall (3) and (4); the inexact GMRES method ends up with (the norm of) the computed residual

$$
\tilde{r}_{m}=r_{0}-V_{m+1} \bar{H}_{m} y_{m}
$$

while the true residual satisfies

$$
\begin{align*}
r_{m} & =b-A x_{m}=b-A\left(x_{0}+V_{m} y_{m}\right) \\
& =\tilde{r}_{m}+\left[E_{1} v_{1}, \ldots, E_{m} v_{m}\right] y_{m} . \tag{5}
\end{align*}
$$

In the exact case where all the $E_{k}=0$, the two residuals coincide, $\tilde{r}_{m}=r_{m}$, and it is well known that the norm can be retrieved economically from the Givens rotations that are created to reduce the Hessenberg matrix $\bar{H}_{m}$ to triangular form. In the inexact case, however, there is an unknown residual gap between the true residual and the computed residual, and from (5) this gap satisfies

$$
\begin{equation*}
\delta_{m}=\left\|r_{m}-\tilde{r}_{m}\right\|_{2}=\left\|\left[E_{1} v_{1}, \ldots, E_{m} v_{m}\right] y_{m}\right\|_{2} \tag{6}
\end{equation*}
$$

The inexact solver still reports $\left\|\tilde{r}_{m}\right\|_{2}$ as the estimate of the residual, but the gap between this estimate and the true residual is not obvious, prompting a reservation about the reliability of the final solution. Clearly, monitoring $\delta_{m}$, or its relative counterpart, $\delta_{m} /\|A\|_{2}\left\|y_{m}\right\|_{2}$, which is more meaningful as a backward error criterion (see [7]), becomes necessary. This is discussed next.

### 2.2. Monitoring the inexact matrix-vector product

Letting $\eta_{k}^{(m)}$ be the $k$ th component of $y_{m}$, i.e.,

$$
y_{m}=\left(\eta_{1}^{(m)}, \eta_{2}^{(m)}, \ldots, \eta_{m}^{(m)}\right)^{T}
$$

if follows from (5) that $\left\|r_{m}\right\|_{2} \leq\left\|\tilde{r}_{m}\right\|_{2}+\delta_{m}$ with

$$
\begin{equation*}
\delta_{m} \leq \sum_{k=1}^{m}\left|\eta_{k}^{(m)}\right| \cdot\left\|E_{k} v_{k}\right\|_{2} \leq \sum_{k=1}^{m}\left|\eta_{k}^{(m)}\right| \cdot\left\|E_{k}\right\|_{2} \tag{7}
\end{equation*}
$$

and we note in passing that this bound is observed to be often sharper than using

$$
\delta_{m}=\left\|\left[E_{1} v_{1}, \ldots, E_{m} v_{m}\right] y_{m}\right\|_{2} \leq\left\|\left[E_{1} v_{1}, \ldots, E_{m} v_{m}\right]\right\|_{2} \cdot\left\|y_{m}\right\|_{2} .
$$

It also explains why the error in the matrix-vector product can be large provided that either of the products $\left|\eta_{k}^{(m)}\right| \cdot\left\|E_{k} v_{k}\right\|_{2}$ or $\left|\eta_{k}^{(m)}\right| \cdot\left\|E_{k}\right\|_{2}$ is small. But a major difficulty here is that $y_{m}$ is only available at the $m$ th iteration and so, as the iterations unfold, it is not clear how to determine the maximum allowable error at the $k$ th iteration that can ultimately guarantee that the upcoming gap $\delta_{m}$ at the $m$ th iteration stays within a prescribed tolerance. To address this problem, Simoncini and Szyld [7] attempted to bound $\left|\eta_{k}^{(m)}\right|$ in terms of quantities that are available at the $k$ th iteration. They showed that the following inequality holds:

$$
\begin{equation*}
\left|\eta_{k}^{(m)}\right| \leq \frac{1}{\sigma_{\min }\left(\bar{H}_{m}\right)}\left\|\tilde{r}_{k-1}\right\|_{2} \tag{8}
\end{equation*}
$$

where $\sigma_{\min }\left(\bar{H}_{m}\right)=\left\|\left(\bar{H}_{m}^{T} \bar{H}_{m}\right)^{-1}\right\|_{2}^{-1 / 2}$ is the smallest singular value of $\bar{H}_{m}$. Therefore if we can somehow enforce the extent of the inexactness in the matrix-vector products to satisfy

$$
\begin{equation*}
\left\|E_{k}\right\|_{2} \leq \frac{\sigma_{\min }\left(\bar{H}_{m}\right)}{m} \frac{\varepsilon}{\left\|\tilde{r}_{k-1}\right\|_{2}}, \quad k=1, \ldots, m \tag{9}
\end{equation*}
$$

for a prescribed $\varepsilon$, we will automatically get from (7)

$$
\delta_{m}=\left\|r_{m}-\tilde{r}_{m}\right\|_{2} \leq \varepsilon .
$$

The bound (9) explains why the greater the iteration number $k$ is, the smaller $\left\|\tilde{r}_{k-1}\right\|_{2}$ gets (in those cases where there is no stagnation), and so the larger the allowable error $E_{k}$ in the matrix-vector product could be. However, while all the intermediate computed residuals $\left\|\tilde{r}_{k-1}\right\|_{2}$ are readily available via Givens rotations as we hinted earlier, the difficulty now has shifted to anticipating what $\sigma_{\min }\left(\bar{H}_{m}\right)$ might end up being, prior to reaching the $m$ th iteration. This remains an open question and it is suggested in [7] that one use an estimate, e.g., $\sigma_{\min }\left(\bar{H}_{m}\right) \approx \sigma_{\min }(A)$, the smallest singular value of $A$. This issue is discussed further in [8], but their bounds are still not ideal in our case where $n \gg 1$ since we deal with very large problems. Another practical difficulty is that it may not be easy to measure and fine-tune $\left\|E_{k}\right\|_{2}$ (or more likely an approximation thereof). Thus the cost of monitoring a relaxation strategy may build up to a non-negligible amount when dealing with very large matrices over thousands of steps.

Our study is motivated by the aspects above. We will measure the actual computational time and illustrate how the gap evolves in representative examples. We will describe a simple but effective strategy for performing the relaxation based on controlling $\left\|E_{k} v_{k}\right\|_{2}$ in (7) using a parameter called droptol. Conceptually, our strategy amounts to dropping a number of elements in the matrix, therefore making the matrix more sparse. This causes $E_{k}$ to be the elements that were dropped and we can pick a droptol that restricts $\left\|E_{k} v_{k}\right\|_{2}$ in a number of ways. This is discussed in Section 3 but we would like to first raise other aspects that are worth keeping in mind in an inexact setting, especially for those wishing to use inexact GMRES in their applications.

### 2.3. Restart and loss of optimality

Since inexact versions of GMRES are likely to come from modifying existing exact codes, there need to be a few extra adjustments beside the inexact matrix-vector product in order for the data to be accurately reported using the theory in [7] that was summarized above. The derivation of the gap assumes that the initial residual $r_{0}$ is exact (or at the very least within the tolerance desired on the solution; see the discussion at the end of [7, Section 3]). The theory does not hold if this assumption is overlooked. Yet, this is precisely what happens at restart if an exact code is converted to an inexact code by merely relaxing the matrix-vector product routine. A simple way to understand what happens is to recall that the exact GMRES method seeks to solve

$$
\min \left\|b-A x_{m}\right\|_{2}=\min \left\|b-A\left(x_{0}+z_{m}\right)\right\|_{2}=\min \left\|r_{0}-A z_{m}\right\|_{2}
$$

which yields $z_{m}=V_{m} y_{m}$ with $y_{m}=\bar{H}_{m}^{\dagger}\left(\beta e_{1}\right), \beta=\left\|r_{0}\right\|_{2}$, and $\bar{H}_{m}^{\dagger}$ being the pseudo-inverse of $\bar{H}_{m}$. Thus if we substitute $r_{0}$ with a very distant $\tilde{r}_{0}=b-\left(A+E_{0}\right) x_{0}$ where the perturbation $E_{0}$ is large, we end up solving

$$
\min \left\|\tilde{r}_{0}-A \tilde{z}_{m}\right\|_{2}
$$

for some $\tilde{z}_{m}$ that ends up distant from the intended $z_{m}$. This is the effect that could happen in the inexact setting, and understandably, analyzing the residual gap serves little purpose in such a situation. It is easy to overlook this when converting an exact code to be inexact because, as we mentioned before, the exact GMRES commonly implements the shortcut method $r_{0} \leftarrow r_{m}:=r_{0}-V_{m} \bar{H}_{m} y_{m}$ at restart, and we explained earlier that this does not match the true residual in the inexact case. Thus a completely inexact code is hard to achieve because the need for the true residual at restart is inevitable. The importance of an accurate residual at restart has also been discussed in the context of the Newton-GMRES algorithm for solving nonlinear problems [9]. At the very least, we recommend computing the true residual upon completion to double-check the accuracy of the solution when the inexact solver claims convergence. In our experiments, we changed the restart of the SLAP code to compute the residual explicitly using a full blown matrix-vector product

$$
r_{0} \leftarrow r_{m}:=b-A x_{m}
$$

Even when using the exact computation of the residual at restart there are still some instances where the behavior of inexact GMRES can markedly differ from what practitioners have come to expect with exact GMRES, notably the core tenet that the norm of the true residual never increases in exact GMRES. The opposite can happen in inexact GMRES, manifested by an erratic sequence of the norms of its corresponding true residual. This means that inexact GMRES loses the optimality of exact GMRES. To understand why, assume that $y_{m}^{\mathrm{opt}}$ is the vector that would have achieved the exact minimization of the true residual as

$$
\left\|r_{m}^{\mathrm{opt}}\right\|_{2}=\left\|r_{0}-A V_{m} y_{m}^{\mathrm{opt}}\right\|_{2}=\min _{y}\left\|r_{0}-A V_{m} y\right\|_{2}
$$

upon constructing the basis $V_{m}$ through the inexact process (4). We have actually replaced the exact minimization of the residual with an approximation that can be described as

$$
\begin{aligned}
y_{m}^{\mathrm{opt}} & =\arg \min _{y}\left\|r_{0}-A V_{m} y\right\|_{2} \\
& =\arg \min _{y}\left\|\left(r_{0}-V_{m+1} \bar{H}_{m} y\right)+F_{m} y\right\|_{2} \\
& \approx \arg \min _{y}\left\|r_{0}-V_{m+1} \bar{H}_{m} y\right\|_{2} \\
& =y_{m} .
\end{aligned}
$$

Thus even if $r_{0}, y_{m}$ and the corresponding true residual $r_{m}$ are computed accurately, there is no guarantee that $y_{m}$ (resp. $r_{m}$ ) will be close to $y_{m}^{\mathrm{opt}}$ (resp. $r_{m}^{\mathrm{opt}}$ ). A small gap $\left\|F_{m} y_{m}\right\|_{2}$ does not rule out this issue either because it could just be that $y_{m}$ is almost in the null space of $F_{m}$ with $r_{m}$ already very different from $r_{m}^{\mathrm{opt}}$. This latter scenario is expected to be rare however.

Again the point is not that inexact GMRES is not minimizing the residual due to the way its basis was constructed, but rather that it is not even getting the minimizer of the residual from within its own basis, and this means that inexact GMRES should be viewed much like a quasi-minimum residual method. Our experiments include illustrative plots of $\left\|y_{m}^{\text {opt }}-y_{m}\right\|_{2}$ and $\left\|r_{m}^{\text {opt }}-r_{m}\right\|_{2}$. See Figs. 12-14.

Finally, we should clarify that the computed residual can also have an erratic behavior but in a more subtle way. Indeed the computed residual always remains monotonic until the maximum size of the basis is reached because

$$
\left\|\tilde{r}_{0}\right\|_{2} \geq \cdots \geq\left\|\tilde{r}_{k}\right\|_{2}=\min _{y}\left\|r_{0}-V_{k+1} \bar{H}_{k} y\right\|_{2} \geq \cdots \geq\left\|\tilde{r}_{m}\right\|_{2}=\min _{y}\left\|r_{0}-V_{m+1} \bar{H}_{m} y\right\|_{2}
$$

But since the computed residual is reset to the true residual at restart, this has the effect of creating an impulse if the gap is perceptible, giving the appearance of an erratic behavior. If an implementation chooses not to reset the computed residual to the true residual at restart or if the gap remains negligible throughout the restarts, then the computed residual will remain monotonic. In the case where the computed residual is not reset, the danger is that it may end up small by monotonicity when in reality the true residual is large, misleading the user into accepting an inaccurate solution. This is why we recommend at least computing a sufficiently accurate residual at completion to confirm the accuracy of the final solution.

## 3. Practical implementation

We saw that the effectiveness of the inexact scheme is tied to the residual gap

$$
F_{m} y_{m}=\left[E_{1} v_{1}, \ldots, E_{m} v_{m}\right] y_{m}
$$

We implemented two strategies for the inexact matrix-vector product by dropping operations that would otherwise involve elements of very small magnitude. In this section we discuss how the errors introduced by our schemes relate to the theoretical bounds seen earlier.

### 3.1. Inexact matrix-vector products

In the first strategy, writing

$$
A=\left[a_{1}|\ldots| a_{n}\right], \quad v=\left(\mu_{1}, \ldots, \mu_{n}\right)^{T}
$$

where the $a_{j} \in \mathbb{R}^{n}$ and $\mu_{j} \in \mathbb{R}$ for $j=1, \ldots, n$, we perform our matrix-vector product in the following column-oriented way:

$$
A v=\left[a_{1}|\ldots| a_{n}\right]\left[\begin{array}{c}
\mu_{1} \\
\vdots \\
\mu_{n}
\end{array}\right]=\sum_{j \in J} \mu_{j} a_{j}+\sum_{j \in J^{c}} \mu_{j} a_{j}
$$

where $J$ is the set of indices such that $\left|\mu_{j}\right|>d r o p t o l$ and $J^{c}$ is its complement, with droptol being a user-specified tolerance. We then use the approximation

$$
\begin{equation*}
A v \approx \sum_{j \in J} \mu_{j} a_{j} \tag{10}
\end{equation*}
$$

which conceptually amounts to dropping selected columns of the matrix $A$ and entails the error

$$
E v=\sum_{j \in J^{c}} \mu_{j} a_{j}
$$

and so for any norm $\|\cdot\|$, since $J^{c}$ is the set of indices such that $\left|\mu_{j}\right| \leq$ droptol, we have

$$
\begin{equation*}
\|E v\| \leq \sum_{j \in J^{c}}\left|\mu_{j}\right| \cdot\left\|a_{j}\right\| \leq \sum_{j \in J^{c}} \text { droptol } \cdot\left\|a_{j}\right\| \leq \text { droptol } \cdot\left|J^{c}\right| \cdot\|A\| \tag{11}
\end{equation*}
$$

where $\left|J^{c}\right|$ denotes the cardinality of $J^{c}$. A large $\left|J^{c}\right|$ would imply the presence of many small $\mu_{j}$ (in magnitude), meaning that several columns have been dropped in the matrix-vector product, thereby leading to substantial savings provided that these columns had many non-zero elements.

In the context of inexact GMRES for a large sparse problem, the Arnoldi process computes

$$
w_{k}=\left(A+E_{k}\right) v_{k}
$$

where $v_{k}=\left(\mu_{1}^{(k)}, \ldots, \mu_{n}^{(k)}\right)^{T}$ is a normalized basis vector with $\left\|v_{k}\right\|_{2}=1$. It is very likely that some components are very small since $\sum_{j=1}^{n}\left(\mu_{j}^{(k)}\right)^{2}=1$ with $n \gg 1$. Hence, the larger the $n$, the smaller the components (in magnitude) and the more of them there will be, and in the light of the previous discussion, this will result in substantial savings in the cost of our inexact matrix-vector product provided that the corresponding columns of the matrix that we drop have many non-zero elements.

As $\left|J^{c}\right|$ grows large and brings more savings, the error bound (11) may become too loose to be useful. This is because it caters for any norm and so is too general. A tighter bound is summarized below.

Theorem 1. The residual gap resulting from the inexact GMRES method based on the relaxed matrix-vector product (10) satisfies

$$
\frac{\left\|F_{m} y_{m}\right\|_{\infty}}{\|A\|_{\infty}\left\|y_{m}\right\|_{1}} \leq \text { droptol }
$$

Proof. First note that the error from (10) can be bounded as

$$
\begin{equation*}
\|E v\|_{\infty} \leq \text { droptol } \cdot\|A\|_{\infty} \tag{12}
\end{equation*}
$$

which gives a clearer picture of the actual accuracy being traded. This bound comes from the fact that we can write $E v=A v^{c}$ where $v^{c}$ denotes the vector such that the $j$ th component is the same as $\mu_{j}$ if $j \in J^{c}$; thus $\left|e_{j}^{T} v^{c}\right|=\left|e_{j}^{T} v\right|=\left|\mu_{j}\right| \leq d r o p t o l$, and is 0 otherwise. Recall that $y_{m}=\left(\eta_{1}^{(m)}, \eta_{2}^{(m)}, \ldots, \eta_{m}^{(m)}\right)^{T}$; we can infer from (12) that

$$
\left\|F_{m} y_{m}\right\|_{\infty} \leq \sum_{k=1}^{m}\left|\eta_{k}^{(m)}\right| \cdot\left\|E_{k} v_{k}\right\|_{\infty} \leq \text { droptol } \cdot\|A\|_{\infty} \sum_{k=1}^{m}\left|\eta_{k}^{(m)}\right|=\text { droptol } \cdot\|A\|_{\infty}\left\|y_{m}\right\|_{1}
$$

which produces the relative form stated in the theorem.

Recall (8); we can also conclude that

$$
\left\|F_{m} y_{m}\right\|_{\infty} \leq \frac{\text { droptol } \cdot\|A\|_{\infty}}{\sigma_{\min }\left(\bar{H}_{m}\right)} \sum_{k=1}^{m}\left\|\tilde{r}_{k-1}\right\|_{2}
$$

and this shows that

$$
\left\|F_{m} y_{m}\right\|_{\infty} \leq \epsilon\|A\|_{\infty}
$$

where

$$
\epsilon \leq \text { droptol } \cdot\left\|y_{m}\right\|_{1} \leq \frac{\text { droptol }}{\sigma_{\min }\left(\bar{H}_{m}\right)} \sum_{k=1}^{m}\left\|\tilde{r}_{k-1}\right\|_{2},
$$

where we can make $\epsilon \in(0,1)$ by choosing a sufficiently small droptol. Therefore we have now provided an error bound for our inexact scheme using the parameter $\epsilon$ and $\|A\|_{\infty}$ where $\epsilon$ depends on values from our iterations and so cannot be pre-determined for all problems exactly. A similar technique can be seen in [7].

Our first strategy applied a droptol to the components of a basis vector $v$ in the inexact product $w \approx A v$. However this strategy did not weight the components of $v$, where $v=\left(\mu_{1}, \ldots, \mu_{n}\right)^{T}$, with the matrix $A=\left[a_{1}|\ldots| a_{n}\right]$. When we drop $\mu_{j} a_{j}$ in our matrix-vector product with $\left|\mu_{j}\right| \leq d r o p t o l$, it is possible, on one hand, for $\left\|\mu_{j} a_{j}\right\|_{\infty}$ to be large enough to contribute significantly to the error; on the other hand, if the column $a_{j}$ only has small elements, since $\mu_{j}<1$, it is possible for $\mu_{j} a_{j}$ to shrink enough to become negligible even if $\left|\mu_{j}\right|>d r o p t o l$. Therefore a second strategy is to use a weighted threshold where the combination of $\mu_{j} a_{j}$ is omitted in the matrix-vector product if

$$
\left|\mu_{j}\right| \cdot\left\|a_{j}\right\|_{\infty} \leq \text { droptol }
$$

In this case, the matrix-vector product becomes

$$
A v=\sum_{j \in J_{w}} \mu_{j} a_{j}+\sum_{j \in J_{w}^{c}} \mu_{j} a_{j}
$$

where $J_{w}$ is the set of indices such that $\left|\mu_{j}\right| \cdot\left\|a_{j}\right\|_{\infty}<d r o p t o l$. As before we use the approximation

$$
\begin{equation*}
A v \approx \sum_{j \in J_{w}} \mu_{j} a_{j} \tag{13}
\end{equation*}
$$

which has the error

$$
E v=\sum_{j \in J_{w}^{c}} \mu_{j} a_{j},
$$

but this time

$$
\|E v\|_{\infty} \leq \sum_{j \in J_{w}^{c}}\left|\mu_{j}\right| \cdot\left\|a_{j}\right\|_{\infty} \leq \sum_{j \in J_{w}^{c}} \text { droptol } \leq\left|J_{w}^{c}\right| \cdot \text { droptol } .
$$

Thus this scheme uses droptol in a way that takes into consideration the entries of our matrix whereas the previous scheme did not. We can express the bound without $\left|J_{w}^{c}\right|$ in the following way.

Theorem 2. Let $A_{w}(v)$ be the matrix derived from $A=\left[a_{i j}\right]$ and $v=\left(\mu_{1}, \ldots, \mu_{n}\right)^{T}$ such that its $i j t h$ entry is $\mu_{j} a_{i j}$ if it is less than droptol in magnitude and 0 otherwise. Then the residual gap resulting from the inexact GMRES method based on the relaxed matrix-vector product (13) satisfies

$$
\frac{\left\|F_{m} y_{m}\right\|_{\infty}}{\left\|y_{m}\right\|_{1}} \leq \max _{1 \leq k \leq m}\left\|A_{w}\left(v_{k}\right)\right\|_{\infty} \leq \text { droptol } \cdot\left\|\mathbb{1}_{A}\right\|_{\infty},
$$

where $\mathbb{1}_{A}$ is the sparsity pattern of $A$, with 1 at the non-zero positions and 0 elsewhere.
Proof. It follows from the definition of $A_{w}(v)$ that the error due to (13) satisfies

$$
E v=\sum_{j \in J_{w}^{c}} \mu_{j} a_{j}=A_{w}(v) e, \quad e=(1, \ldots, 1)^{T},
$$

with $\left|e_{i}^{T} A_{w}(v) e_{j}\right|=\left|\mu_{j} a_{i j}\right| \leq d r o p t o l$ if $j \in J_{w}^{c}$ and 0 otherwise. And so

$$
\|E v\|_{\infty} \leq\left\|A_{w}(v)\right\|_{\infty}
$$

Like with the previous theorem, we get

$$
\begin{aligned}
\left\|F_{m} y_{m}\right\|_{\infty} & \leq \sum_{k=1}^{m}\left|\eta_{k}^{(m)}\right| \cdot\left\|E_{k} v_{k}\right\|_{\infty} \leq \sum_{k=1}^{m}\left|\eta_{k}^{(m)}\right| \cdot\left\|A_{w}\left(v_{k}\right)\right\|_{\infty} \\
& \leq\left\|y_{m}\right\|_{1} \cdot \max _{1 \leq k \leq m}\left\|A_{w}\left(v_{k}\right)\right\|_{\infty}
\end{aligned}
$$

Since entries of $A_{w}(v)$ are less than droptol in magnitude, the stated inequality follows.

Table 1
Characteristics of the problems (*symmetric problem, but symmetry is not exploited here). $\|A\|_{2}^{\text {est }}$ was estimated by the function call normest( $A$ ) in MATLAB. These matrices come from The University of Florida Sparse Matrix Collection [11].

The matrix $A_{w}(v)$ symbolizes all the elements that were not included in the weighted matrix-vector product (13), with these elements further scaled down by the corresponding $\mu_{j}$. If the matrix $A$ already had small elements, it is possible for $A_{w}(v)$ to capture many of them (which means many savings in the matrix-vector product). But if $A$ had large elements, there may not be that much saving, unless $\mu_{j} \ll 1$ and droptol is not stringent. This is different from the first scheme where a large $n$ assured many small $\mu_{j}$, which then virtually assured savings. The sparsity pattern of $A_{w}(v)$ is a subset of that of $A$ and we have $\left\|A_{w}\left(v_{k}\right)\right\|_{\infty} \leq\|A\|_{\infty}$, but not necessarily $\left\|A_{w}\left(v_{k}\right)\right\|_{\infty} \leq$ droptol $\cdot\|A\|_{\infty}$.

Our dropping strategies are columnwise and so we converted the test matrices into the Compressed Column Storage (CCS) format, which is the most suitable compact format in our context. We implemented the weighted scheme by computing all the $\left\|a_{j}\right\|_{\infty}$ at the very beginning and re-using them throughout the computations. Trying to implement a finer strategy would mean scanning the entire matrix at each matrix-vector product, which will be very much prohibitive.

### 3.2. Savings

Let us denote the number of non-zero elements of the $j$ th column of our matrix $A$ by $n z\left(a_{j}\right)$. Therefore when we skip the product of $\mu_{j} a_{j}$ in either of our schemes, we are saving $n z\left(a_{j}\right)$ floating point operations. Now, considering the entire matrix, we are saving $\sum_{j \in J^{c}} n z\left(a_{j}\right)$ operations (substitute $J^{c}$ with $J_{w}^{c}$ as appropriate for the weighted scheme). Recall that this means that we skip $J^{c} \mid$ columns. Consequently we can expect meaningful savings only if the values of $n z\left(a_{j}\right)$ are not too small on average and if $\left|J^{c}\right| \gg 1$. This explains why when we considered cases where $n \leq 10,000$, the savings were not that significant because $\left|J^{c}\right|$ was not that large when one takes account of today's very fast CPUs. Moreover, even for larger problems, if the $n z\left(a_{j}\right)$ are small on average, we do not see any savings worth using inexact matrix-vector products for, because the cost of deciding whether or not to use a column (using a conditional if-check) must be compensated for by the savings generated by that column, and this can only happen if $n z\left(a_{j}\right) \gg 1$. Therefore we will focus our experiments on large problems in which we additionally have $n z\left(a_{j}\right) \gg 1$. We provide histograms of $n z\left(a_{j}\right)$ in our results to give the reader a sense of the distribution of the non-zeros. The importance of this consideration was also observed in [10].

## 4. Numerical results

All calculations were done on a supercomputer hosted at the Alabama Supercomputer Center (ASC) in Huntsville, Alabama. The ASC hosts units of two types: the Dense Memory Cluster (DMC) and the SGI Altix. At the time of our experiments the DMC has 1256 CPU cores and 6176 GB of distributed memory. The machine is physically configured as a set of eight CPU core SMP boards. Sixty of the nodes have 64 GB of memory. Twenty nodes have 3.0 GHz dual-core AMD Opteron processors. Forty nodes have 2.3 GHz quad-core AMD Opterons. Ninety-six nodes have 2.26 GHz Intel quad-core Nehalem processors. Our executions were done in batch mode on the DMC and the batch system automatically assigns the job to a CPU core depending on the queue. Table 1 lists the characteristics of the problems used in our experiments.

Our results are detailed in the Appendix. We set the true solution $x=(1,0, \ldots, 0,1)^{T}$ and generate the right side $b=A x$ for each problem. Hence we can test the true error $\left\|x-x_{m}\right\|_{2}$ on completion. For ease of presentation of the results, we use the index $m$ (as in $x_{m}$ ) to denote the final iterate, even though there could have been intermediate restarts and/or the convergence could have occurred midway during the iterations, as is often the case with GMRES. In the SLAP solver, we set the restart parameter $m=50$ and request an accuracy tolerance tol $=10^{-6}$ everywhere. Convergence means that $\left\|\tilde{r}_{m}\right\|_{2} /\|b\|_{2} \leq t o l$. We set 2500 as the maximum overall number of iterations (the current number of iterations is not reset at restart and so is not bounded by $m$ ).

For each set of results, we give:

- The histogram of the distribution of non-zero entries per column of the matrix under consideration. Thus with $n z\left(a_{j}\right)$ indicating the number of non-zeros in the column, \#cols represents the number of columns of the matrix that have this indicated number of non-zeros. This preparatory information is very useful because it allows one to predict the potential
savings in the inexact matrix-vector products as we explained earlier. If the histogram shows that most columns have few non-zero entries then we can expect no significant difference, as far as time is concerned, to motivate using the inexact scheme. This is why we focused on large problems where the $n z\left(a_{j}\right)$ are not too small. We observed in general that if a high number of columns have more than 10 non-zero entries, the matrix will be more likely to make the inexact scheme worthwhile on our testing platform. On the basis of such preparatory information and depending on their environment, practitioners may decide whether our inexact matrix-vector strategies are suitable for their applications in terms of savings in computational time.
- The data collected from the execution, with the CPU time coming from the optimized code and the debugging data from the separate instrumentation code as we described at the beginning.
- droptol: relaxation parameter in the inexact matrix-vector as detailed in Section 3.1.
- $\left\|x-x_{m}\right\|_{2} /\|x\|_{2}$ : true error in the final computed solution.
- $\left\|r_{m}\right\|_{2} /\|b\|_{2}$ : true residual on completion.
- $\left\|\tilde{r}_{m}\right\|_{2} /\|b\|_{2}$ : computed residual on completion (note that our implementation reset $\tilde{r}_{0}$ to the true residual $r_{0}$ at restart positions).
- $\delta_{m}$ : residual gap on completion, $\delta_{m}=\left\|r_{m}-\tilde{r}_{m}\right\|_{2}$.
- Runtime (s): CPU time in seconds.
- \#Iter: number of iterations (not to be confused with the number of restarts). It is incremented every time a new approximated solution is possible (even if it is not computed explicitly-as is the case with GMRES) and is not reset at restart. Convergence failure is declared if \#Iter reaches 2500 without the computed residual meeting the convergence criteria.
- Savings: number of operations saved. This is a counter that is incremented with $n z\left(a_{j}\right)$ if the $j$ th column is skipped in our inexact matrix-vector product.
- Graphical plots of the history of the residual norm (scaled by $\|b\|_{2}$ ) when using either the unweighted matrix-vector product and the weighted alternative.

For a few problems (Figs. 12-14) we plot the history of some of their characteristics throughout the entire run with droptol $=10^{-3}$, including the residual gap $\delta_{m}$, as well as $\left\|y_{m}^{\mathrm{opt}}-y_{m}\right\|_{2}$ and $\left\|r_{m}^{\mathrm{opt}}-r_{m}\right\|_{2}$ that give an idea of the quasiminimization that takes place within inexact GMRES. Fig. 13 is an example where inexact GMRES (with droptol $=10^{-3}$ ) claimed early convergence (after only six iterations), whereas it appears clear from the history of its attributes in Fig. 5 that the residual gap was not within the requested tolerance.

We run the experiments with droptol ranging from $10^{-3}$ to $10^{-10}$, and the results show that only when droptol $=10^{-3}$ does the inexact scheme show most of its perceptible accuracy difficulties. This shows that the inexact scheme is fairly robust as far as accuracy is concerned. The smaller droptol is, the closer inexact GMRES gets to the exact GMRES. It is remarkable how in many problems the plots of the residual norm became almost indistinguishable at droptol $=10^{-5}$ and lower.

We did not vary the accuracy per iteration, but the fact that we use a wide range of droptol provides similar evidence that starting with droptol $=10^{-10}$ and relaxing gradually within the iterations would have worked equally well, as predicted by the theory and experiments by previous authors. We did not also consider preconditioners as they would have introduced other parameters that would have increased the number of experiments beyond our already large set.

Problems cage 13 and cage 14 show identical behaviors although the latter is twice as big as the former. The same can be said about cfd1 and cfd2. Problem ebp3 is peculiar in that it makes the inexact scheme diverge when the weighted matrix-vector product is used. This is due to the fact that its matrix is of small norm, $\|A\|_{\infty}=0.68$, and as we discussed in Section 3.1, the bigger droptol $=10^{-3}$ causes many elements to fall into the error term of the matrix-vector, making it too inexact. Contrast this with pwtk for which the matrix is of large norm, $\|A\|_{\infty}=1.82 \cdot 10^{8}$, indicating the presence of large elements in the matrix. In this case, it is the unweighted matrix-vector that suffers because it only checks the operand vector and skips columns of the matrix without regard to the magnitude of its elements. The large perturbation that results from this matrix leads to a larger residual gap, which explains the spikes at restart positions that we see in the plot. Spikes appear in general when the computed residual is reset to the true residual at restart positions, but may be imperceptible if the residual gap is too small. They can be seen on some of the other plots as well. Problem pwtk is also a case where none of the schemes converge within the allotted maximum number of iterations, but their residual decreases quite well.

Another example that stands out is circuit_4, where the inexact scheme returns a highly optimistic residual when droptol $=10^{-3}$ under either of the matrix-vector strategies, suggesting that it is a matrix where the perturbations should not be too big at the beginning of the iterations. There are other instances where the computed residual is too optimistic; for example in Table 5 for cage 14, the gap is large when droptol $=10^{-3}$. Protection against such optimistic computed residuals requires at least computing an accurate residual on completion so as not to mislead the user into thinking that the returned solution is as accurate as claimed by the inexact solver.

We noted earlier that the computed residual need not be monotonic. Problem hcircuit is a clear illustration of this under the weighted matrix-vector product.

In results not reported here, we experimented with not computing the restart residual accurately. We saw that it is very risky to adopt this approach because the inexact scheme can subsequently claim convergence when actually this has not been achieved. In such cases the final residual gap remains wide (but it should be recalled that the residual gap is not computed in an optimized setting and therefore users cannot expect to base their decision on its availability). Hence we recommend computing the restart residual at least as accurately as with the tolerance requested for the solution.

| $10^{-6}$ | $2.58 \mathrm{e}-06$ | $1.83 \mathrm{e}-06$ | $4.77 \mathrm{e}-07$ | $1.71 \mathrm{e}-06$ | 1.49 | 18 |  |
| $10^{-8}$ | $1.61 \mathrm{e}-06$ | $4.77 \mathrm{e}-07$ | $4.77 \mathrm{e}-07$ | $3.30 \mathrm{e}-09$ | 1.62 | 18 |  |
| $10^{-10}$ | $1.61 \mathrm{e}-06$ | $4.77 \mathrm{e}-07$ | $4.77 \mathrm{e}-07$ | $5.14 \mathrm{e}-12$ | 1.64 | 18 | 18 |

Overall, we can see that both of the inexact schemes are quite robust, leaving the savings only really dependent on the sparsity pattern of the problem and the CPU speed. The savings in floating point operations in many of the problems appear to be quite significant (ranging from several hundreds of thousands to several millions of operations), but with today's very fast CPUs, it takes a fair chunk of work for them to start affecting the CPU time. This is why even though the inexact GMRES with varying droptol is often as accurate as the exact GMRES while having substantial savings, their execution times remain close. It is also why for smaller matrices the time for the exact method and that for the inexact method were so close that there was no need to use an inexact method to help improve efficiency.

## 5. Conclusion

We discussed the inexact GMRES method and presented two strategies for relaxing the matrix-vector product based on a droptol parameter. Conceptually, our inexact strategies amount to dropping a number of elements in the matrix, therefore making it more sparse. We compared them with the exact scheme for a wide range of problems. Our extensive experiments showed that the inexact schemes are competitive with the exact scheme for very large problems, provided that their savings grow enough to become perceptible with today's very fast CPUs. We saw that accuracy was not the main concern with the inexact schemes, if implemented with care. In particular, the uncertainty with the residual gap can be virtually eliminated by computing the true residual at restart positions. Indeed, we used an instrumentation code and plotted the history of the residual norms and they became almost indistinguishable at reasonable droptol. Our analysis provided additional insight into the inexact GMRES method and our experiments provided further data that should assist practitioners in deciding whether switching to inexact GMRES is worthwhile for their applications.

## Appendix A. Results for cage 13

$$
\left.n=445,315 \quad n z=7,479,343 \quad\|A\|_{\infty}=1.41 \quad\|b\|_{2}=9.67 \cdot 10^{1} \quad \text { (see Tables 2, } 3 \text { and Fig. } 1\right) .
$$

## Appendix B. Results for cage 14

$$
n=1,505,785 \quad n z=27,130,349 \quad\|A\|_{\infty}=1.33 \quad\|b\|_{2}=9.58 \cdot 10^{1} \quad(\text { see Tables } 4,5 \text { and Fig. 2). }
$$

## Appendix C. Results for cfd1

$n=70,656 \quad n z=1,828,364 \quad\|A\|_{\infty}=8.92 \quad\|b\|_{2}=2.15 \quad$ (see Tables 6, 7 and Fig. 3).
