#### Abstract

We review approximability and inapproximability results for MIN-SUM scheduling problems and we focus on techniques for designing polynomial time approximation schemes for this class of problems. We present examples which illustrate the efficient use of the ratio partitioning and time partitioning techniques. © 2005 Elsevier B.V. All rights reserved.

Keywords: Scheduling; MIN-SUM criteria; Approximation algorithms; PTASs

## 1. Introduction

In a scheduling problem, a set of $n$ jobs and a set of $m$ machines are given. We want to schedule these jobs on the machines. A schedule is an assignment of time slots in a machine to each job so that certain constraints are satisfied. An optimal schedule is the one that minimizes a given objective function. Depending on the constraints and the objective function, many variants of the problem can be obtained. In simple variants, the data associated with each job $j$ is its processing time, $p_{j}^{(i)}$, on each machine $i$. Objective functions are defined in terms of the completion time of each job. The completion time $C_{j}$ of job $j$ is the time at which the job completes its execution. The most common objective functions are the maximum completion time over all jobs, called also makespan of the schedule, and the sum of completion times.

Example. We are given a set of jobs $\left\{J_{1}, J_{2}, J_{3}, J_{4}, J_{5}\right\}$ and processing times $3,1,2,3,2$, respectively. Also we have two identical (hence the processing times of jobs are independent of the machine on which they are executed) machines available, $\left\{M_{1}, M_{2}\right\}$. Suppose we decide on scheduling $S_{1}$ which assigns jobs $J_{1}, J_{2}, J_{3}$ on machine $M_{1}$ and in this order, i.e., job $J_{1}$ completes at time $C_{1}=3$, job $J_{2}$ completes at time $C_{2}=4$, and job $J_{3}$ completes at time $C_{3}=6$. The rest of the jobs are assigned to machine $M_{2}$ so that job $J_{4}$ completes at time $C_{4}=3$ and job $J_{5}$ completes at time $C_{5}=5$. For a visualization of this schedule see the Gantt chart in Fig. 1. Gantt charts are convenient means of describing a schedule.

Then the makespan, i.e. the maximum completion time, is equal to 6 . The same makespan can be achieved by the following schedule $S_{2}$ which assigns jobs $J_{2}, J_{3}, J_{5}$ to machine $M_{1}$ and in this order, and the rest to machine $M_{2}$. It is clear that both schedules are optimal for the objective function $\max _{j} C_{j}$ which defines the makespan.

[^0]

Fig. 1. Gantt chart for schedule $S_{1}$.

However, if we sum the completion times on schedule $S_{1}$, we get $3+4+6+3+5=21$ which is not optimal because we can swap jobs $J_{1}$ and $J_{2}$ on machine $M_{1}$ and reduce this sum to $1+4+6+3+5=19$. Schedule $S_{2}$ has sum of completion times 18 . Finally it is easy to see that, in the case we want to minimize the sum of completion times, $\sum_{j} C_{j}$, then the best schedule is $S_{3}$, defined by the following assignment: machine $M_{1}$ is assigned jobs $J_{2}, J_{3}, J_{1}$ and machine $M_{2}$ is assigned jobs $J_{5}, J_{4}$; the sum of completion times in this case is 17 . Schedule $S_{3}$ may be produced by rearranging jobs within machines on scheduling $S_{1}$. Observe, however, that there is no way to get an optimal schedule for the objective function sum-of-completion-times by rearrangement within machines starting from schedule $S_{2}$.

Besides the processing times of jobs a variety of other constraints may be imposed on the set of jobs such as release dates, due dates, weights and precedence constraints. A release date, $r_{j}$, represents the time the job $j$ arrives in the system, that is, the earliest time at which the job can start its execution. A due date, $d_{j}$, represents a committed completion time of the job $j$. The completion of the job after this time is allowed, but usually a penalty is incurred. When the due date absolutely must be met, it is referred to as a deadline. Finally, a weight, $w_{j}$, is a positive integer and represents the importance of job $j$ relative to the other jobs in the system. Thus, when jobs have not the same importance, then an objective function that is more realistic to minimize is the weighted sum of completion times $\sum_{j} w_{j} C_{j}$ instead of the sum of completion times $\sum_{j} C_{j}$.

Precedence constraints express the inter-dependence among jobs that do not allow certain jobs to start being executed before some other jobs have completed their execution. Precedence constraints are described by a partial order, $\prec$, on the set of jobs. If $i \prec j$, then job $j$ can start its execution after the completion of job $i$. We say that jobs are independent if $\prec$ is empty.

Also two different scheduling models are usually considered depending on whether we allow jobs to be interrupted once started (to be resumed later) or not. These are the preemptive schedule, where the execution of a job can be interrupted and continued later on the same or on another machine, and the non-preemptive schedule, where once a job starts executed it should be completed.
According to optimization criteria, scheduling problems can be classified into two broad classes: MIN-MAX criteria and MIN-SUM criteria. The most common MIN-MAX criterion is the maximum completion time (makespan) of the schedule, $\max _{j} C_{j}$, and another is the maximum lateness, $\max _{j}\left(C_{j}-d_{j}\right)$. The most common MIN-SUM criterion is the total (weighted) completion time, $\sum_{j} w_{j} C_{j}$, and another is the total (weighted) flow time, $\sum_{j} w_{j} F_{j}$, where $F_{j}=C_{j}-r_{j}$.

It is well known that only some of the simplest variants of scheduling problems can be solved in polynomial time. Most of the recent research is directed towards designing approximation algorithms for the NP-hard variants of scheduling problems. A $\rho$-approximation algorithm computes polynomially a solution within a factor $\rho$ of the optimum one. In this setting we are interested in designing $\rho$-approximation algorithms with $\rho$ as small as possible as well as on finding lower bounds for $\rho$. When $\rho$ is a constant, then we say that the approximation algorithm is a constant factor one. We say, however, that we have a polynomial time approximation scheme (PTAS) if we give an algorithm which, for any fixed value of $\varepsilon$, can construct an $(1+\varepsilon)$-approximation solution. If the time complexity of a PTAS is also polynomial in $1 / \varepsilon$, then it is called a fully polynomial time approximation scheme (FPTAS). For negative approximation results, the notion of NP-completeness is used to disprove the existence of good approximation algorithms, unless P = NP. It is well known that no strongly NP-hard optimization problem, for which the optimum cost is polynomially bounded with respect to the length of its instance, can have a FPTAS. Also, there is no PTAS for MAX SNP-hard problems, unless $\mathrm{P}=\mathrm{NP}$ (see for example [30]).

Historically, MIN-MAX scheduling problems were the first investigated in the approximation algorithm framework and a lot of results have been proposed after Graham's seminal paper [19]. Most of the early constant approximation
algorithms for MIN-SUM scheduling problems appeared during the 1990s [21,22,31]. However, during the next years, there was much progress on the approximability of MIN-SUM problems, that led to PTASs for many of them.

In this paper we present a survey of this research on approximation algorithms for MIN-SUM scheduling problems, focusing on PTASs design techniques. In Section 2, we give formal definitions and examples for the reader to be introduced to some of the most common known techniques for deriving approximation algorithms for scheduling problems. In Section 3, we review briefly the known constant approximation algorithms by focusing on ideas that were used later for designing PTASs. In Section 4, we present recent results on PTASs and we classify the techniques into two main categories: the ratio partitioning and the time partitioning. These techniques are presented in Sections 5 and 6, respectively, where we give examples which illustrate how they may be used to derive PTASs for various problems. Examples are taken from [3] and [1,2]. We conclude with some open questions in Section 7.

## 2. Background and preliminaries

In this section we first give some detailed definitions to explain the variants of the scheduling problem that we discuss in this paper and some notation. Then we give an introduction to some of the most well known simple algorithms for scheduling problems. In that respect, we present two polynomial algorithms, one constant ratio approximation algorithm and a PTAS.

### 2.1. Basic definitions

In the Introduction we have discussed the general setting for the scheduling problem. However, this applies to many variants and in order to distinguish among them we use the standard three-field, $\alpha|\beta| \gamma$, notation scheme of Graham et al. [20].

The first field describes the machine environment, the second field describes the constraints on jobs and the third field describes the objective function. Thus, the notation $1 \| \sum w_{j} C_{j}$ represents the variant where a number of (independent) jobs are to be executed in one machine and we want to minimize the weighted sum of completion times. The notation $P\left|r_{j}\right| \sum C_{j}$ represents the variant where a number of jobs are to be executed on any given number of identical machines, jobs have release dates (hence are not all available at any time instance) and we want to minimize the sum of completion times. We already discussed and defined in the Introduction the most common constraints on the jobs such us processing times, release dates, deadlines, precedence relation and preemption, which appear in the second field and are denoted by $p_{j}, r_{j}, d_{j}$, prec and pmtn, respectively. We have also discussed the most common objective function which appear in the third field.

The machine environment described by the first field could be, e.g., one of (a) any given number of identical machines, or (b) a fixed number of identical machines or (c) any given number of unrelated (non-identical) machines, and so on. To denote the set of the available machines, we use a standard notation. A single machine environment is denoted by 1. Identical parallel machines are denoted by $P$. In both single machine and identical parallel machines environments the processing time of each job does not depend on the machine and for each job $j$ we are given a single processing time $p_{j}$. Uniformly related parallel machines are denoted by $Q$. In this case for each job $j$ we are given a processing time $p_{j}$ and for each machine $i$ a different speed $s_{i}$. Hence, the time $p_{j}^{(i)}$ job $j$ spends on machine $i$, assuming it is processed only on machine $i$, equals to $p_{j} / s_{i}$. Unrelated parallel machines are denoted by $R$ and in this case we are given a processing time $p_{j}^{(i)}$ for processing each job $j$ on each machine $i$. Thus $\alpha$ takes values from $\{1, P(m), Q(m), R(m)\}$, etc. The optional $m$ denotes a constant number of machines; otherwise, its absence means that the number of machines is part of the problem's instance.

Moreover, in the case of parallel machine environments we might have multiprocessor jobs, where a job can (or need to) be executed simultaneously by several machines. In these case the second field describes also how such jobs can be executed. Thus, the notation $f i x_{j}$ is used for the variant where each job requires the simultaneous use of a prespecified set of machines and the notation size $j_{j}$ for the variant where each job requires any set of machines of a given cardinality. In the general variant denoted by set $_{j}$, each job has a number of processing modes, each one defined by a set of machines and a processing time on this set of machines.

Although, intuitively, might be already understood what is a feasible schedule (e.g., one that does not assign two different jobs on the same machine at the same time), the following is a formal definition. A schedule is, for each job,
an allocation of one or more time intervals to one or more machines. A schedule is feasible if (i) no two time intervals overlap in the same machine, (ii) no two time intervals allocated to the same job overlap (unless it is a multiprocessor job), and (iii) it satisfies the given processing restrictions and constraints. A feasible schedule is optimal if it minimizes the given optimization criterion. The objective value of an optimum solution is denoted by OPT.

### 2.2. Algorithms for simple cases

In this subsection we give simple algorithms (polynomial, constant approximation factor and PTAS) to familiarize the reader with known techniques.

### 2.2.1. Polynomial algorithms

Some simple variants of the scheduling problem have polynomial algorithms. For a thorough listing of complexity results on scheduling problems the reader is referred to the book and a web page of Brucker [5]. We discuss here such a simple polynomial algorithm.

Example: $1 \| \sum w_{j} C_{j}$
The polynomial algorithm that finds an optimal schedule is known as Smith's rule: it schedules according to the rule, "shortest ratio ratio $_{j}=p_{j} / w_{j}$ " first [50]. That is, the algorithm sorts the jobs in non-decreasing order of their ratios and then schedules the jobs on the machine according to this order.

The proof that this algorithm finds an optimal schedule is simple. Let $S$ be an optimal schedule which violates this rule. Suppose the first time the rule is violated is when job $i$ was executed before job $j$ whereas ratio ${ }_{i}>$ ratio $_{j}$. By moving job $j$ to be executed before job $i$ the cost is changed from $A+w_{i} p_{i}+w_{j} p_{i}+w_{j} p_{j}$ (before the moving) to $A+w_{i} p_{i}+w_{i} p_{j}+w_{j} p_{j}$ (after the moving), where $A$ is a quantity which remains the same in the two schedules. Thus, the cost is decreased by $w_{j} p_{i}-w_{i} p_{j}$, hence by swapping jobs $i$ and $j$, we get a better schedule; contradiction.

### 2.2.2. Constant ratio approximation algorithms

A standard technique to obtain a constant time approximation algorithm is to formulate first a (polynomial-time solvable) relaxation of the problem. The relaxations used include preemptive schedules and various linear and convex programs.
Example: $1\left|r_{j}\right| \sum C_{j}$
In the following we present how a preemptive relaxation can be used to approximate the problem $1\left|r_{j}\right| \sum C_{j}$. This result is due to Philips et al. [31]. The problem is first relaxed to its preemptive variant $1\left|r_{j}, p m t n\right| \sum C_{j}$, which is known to be solvable in polynomial time by the shortest remaining processing time (SRPT) rule, i.e. at any point in time, schedule an available job with the least amount of remaining processing time. Let $\tilde{C}_{j}$ be the completion time of job $j$ in this preemptive schedule. A non-preemptive schedule can be obtained by the following heuristic: schedule the jobs in order in which they complete in an optimal preemptive schedule, i.e. in non-decreasing order of $\tilde{C}_{j}$ 's. Consider now the derived non-preemptive schedule and let $C_{j}$ be the completion time of job $j$. For simplicity assume also that the jobs have been scheduled in the order $1,2, \ldots, n$. For each job $j$, let $I_{j}$ be the total amount of idle time before the completion of job $j$ and $P_{j}$ be the total amount of processing time before the completion of job $j$. It clearly holds: $C_{j}=I_{j}+P_{j}$. Now, this quantity can be bounded as follows:

$$
C_{j}=I_{j}+P_{j} \leqslant \max _{k \leqslant j} r_{k}+\sum_{k \leqslant j} p_{k} \leqslant \tilde{C}_{j}+\tilde{C}_{j}=2 \tilde{C}_{j} .
$$

Therefore, $\sum_{j} C_{j} \leqslant 2 \sum_{j} \tilde{C}_{j} \leqslant 2$ OPT.

### 2.2.3. PTAS

Example: $1\left|p_{j}=p, r_{j} \leqslant p \log n\right| \sum C_{j}$
This is a motivating example which is somewhat contrived for the sake of simplicity. We consider the problem $1\left|p_{j}=p, r_{j} \leqslant p \operatorname{logn}\right| \sum C_{j}$, i.e., (i) all $n$ jobs are identical with processing time $p$ and (ii) all release dates are less than plogn. In fact, the more general problem 1|prec, $p_{j}=p, r_{j} \mid \sum C_{j}$ is polynomially solvable [5]. However, in order to make several useful points on the techniques used for PTASs in Section 6, we give the following simple PTAS for $1\left|p_{j}=p, r_{j} \leqslant p \log n\right| \sum C_{j}$.

## Algorithm.

1. If $n \leqslant(1 / \varepsilon)^{2}$, then by exhaustive search find the best schedule.
2. If $n>(1 / \varepsilon)^{2}$, then schedule all jobs after time plogn at any order.

Analysis of the Algorithm: The cost of any optimal schedule is greater than the cost of the schedule $S_{0}$ where all release dates are equal to 0 . In this case, as jobs are identical, we schedule them in any order without idle time and the cost is: Cost $_{0}=\sum_{j=1}^{n} C_{j}=\sum_{j=1}^{n} j p=n(n+1) / 2 p$.

The schedule produced by the algorithm is no worse than adding $\log n$ additional jobs in the end of schedule $S_{0}$. In this case the additional cost is: $\Delta$ Cost $=\log n \max C_{j}+\log n(\log n+1) / 2 p$. However, $\max C_{j}=n p$, hence the algorithm produces a schedule which is worse at most by a ratio:

$$
\frac{\Delta \operatorname{Cos} t}{\operatorname{Cost}_{0}} \leqslant 2 \log n \frac{2}{n+1}<5 \varepsilon
$$

(Here is a detailed but obvious analysis of the very last inequality. Towards contradiction, suppose that $5 \varepsilon<\log n /(n+1)$. This implies $\varepsilon<\log n / n$ which implies $n /(1 / \varepsilon)<\log n$ which implies $\log n-\log (1 / \varepsilon)<\log \log n$, hence $\frac{1}{2} \log n<$ $\log n-\log \log n<\log (1 / \varepsilon)$, hence $\log n<2 \log (1 / \varepsilon)$ or $n<(1 / \varepsilon)^{2}$, contradiction.)
Motivated by this example, we can gain some intuition on how we could move jobs around in a schedule without degrading the cost very much. E.g., in the schedule $S_{0}$ of the jobs in the above analysis, we can (a) Take any job and move it to the end, thus degrading the cost only by an added factor $O\left(C_{j}\right)$, hence by a ratio $2 /(n+1)$, or (b) Take $\log n$ jobs and move them to the end, thus degrading the cost only by an added factor $O\left(C_{j} \log n\right)$, hence by a ratio $\log n(2 / n+1)$.

So, in the general case, we have reason to expect that the following strategy would work: we can shuffle jobs in an "orderly way" without increasing the cost very much, e.g., move a few jobs within the time horizon where jobs of comparable size are executed. We will build on this intuition to solve more complicated problems in Section 6.

## 3. Constant approximation algorithms

Although a FPTAS for $P m\left|\mid \sum w_{j} C_{j}\right.$ (due to Sahni [37]) was known since 1976, only a few approximation algorithms, for a MIN-SUM scheduling problem, have been proposed for some fifteen years. Gonzalez and Sahni in 1978 have proposed approximation results for MIN-SUM shop scheduling problems [18], while Kawaguchi and Kyan in 1986 have shown an 1.21-approximation algorithm for $P \| \sum w_{j} C_{j}$ [24].

The next non-trivial approximation results were an $O\left(\log n \log \sum_{j} w_{j}\right)$-approximation algorithm for $1 \mid$ prec $\mid \sum w_{j} C_{j}$, obtained by Ravi et al. [36], in 1991, which improved to an $O\left(\log n \log \log \sum_{j} w_{j}\right)$ one by Even et al. [14], in 1995. In fact, these results were implied by a general approach proposed in [36] and [14] to build approximation algorithms for ordering problems. Note also that some of these algorithms are still the best known for some ordering problems.

However, little was known about the approximability of MIN-SUM scheduling problems even until 1995, despite the fact that there was an extensive literature on their polyhedral structure (especially of single machine problems). In fact, several linear programming formulations have been considered but they were only exploited either to characterize polynomial solvable special cases or to obtain strong lower bounds allowing the optimal solution of moderate sized problems using enumerative methods (see Queyranne and Schulz [34] for a thorough survey of this research area).
Philips et al. [31], in 1995, gave the first constant approximation algorithms for a number of problems including (8 $+\varepsilon$ )-approximation algorithms for both $1\left|r_{j}, p m t n\right| \sum w_{j} C_{j}$ and $\left.P\left|r_{j}, p m t n\right| \sum w_{j} C_{j}\right)$, a $(16+\varepsilon)$-approximation algorithm for $1\left|r_{j}\right| \sum w_{j} C_{j}$ and a $(24+\varepsilon)$-approximation algorithm for $P\left|r_{j}\right| \sum w_{j} C_{j}$. Subsequently, Hall et al. in [22] and its journal version [21], improved dramatically the known approximation factors and gave algorithms for many new variants. Their results, some of which are the best known even today (see Table 1 below), were motivated by the successful work done on polyhedral structure of scheduling problems and build on earlier research on computing near-optimum solutions for MIN-MAX scheduling problems, by rounding optimum solutions to linear relaxations. In view of future results, the most important point of their work was the introduction of a time-interval indexed LP formulation, since it was proven later very fruitful for designing PTASs for many MIN-SUM problems.

Table 1
Overview of results

| Problem | Best known $\rho$ | (F)PTAS or Lower bound |
| :---: | :---: | :---: |
| $1\left\|r_{j}\right\| \sum C_{j}$ | 1.58 [11] | PTAS [1] |

| $R\left\|r_{j}, p m t n\right\| \sum w_{j} C_{j}$ | $2+\varepsilon$ [35] |  |

[^1]The general idea of time indexed LP formulation was used in the past in several forms. Potts [32] used decision variables $\delta_{i j}$, where $\delta_{i j}$ implies that job $i$ precedes job $j$ in the schedule. Dyer and Wolsey [13] used variables $x_{j t}$, where $x_{j t}=1$ means that job $j$ completes its execution at time $t$. Wolsey [56] and Queyranne [33] used as decision variables the completion times $C_{j}$ of jobs themselves. Hall et al. [22] adopted this last formulation to obtain their results for single machine problems and proposed a different, more compact linear time-interval indexed LP formulation: subdivide the time horizon into the intervals $[1,1],(1,1+\varepsilon],\left(1+\varepsilon,(1+\varepsilon)^{2}\right], \ldots$, where $\varepsilon$ is an arbitrary small positive constant. Then, the linear program only specifies the interval in which the job is completed and since all completion times within an interval are within a $(1+\varepsilon)$ factor of each other, the relative schedule within an interval will be of little consequence. This was the first use of time partitioning.

After the results of Hall et al. [22,21] there has been an explosion of research in this area with new algorithms of successively smaller approximation factors as well as with algorithms for new variants of MIN-SUM scheduling problems. Most of these algorithms follow the general and successful idea of problem relaxation: first an optimum
solution to a relaxation of the original problem is polynomially obtained and then this solution is used to obtain an approximate solution to this problem. Types of relaxations can be distinguished into two broad classes: preemptive scheduling relaxations and several linear and convex programming relaxations. The preemptive scheduling relaxations consist of solving polynomially the preemptive variant of a non-preemptive problem, while the linear and convex programming relaxations consist of relaxing the integer constraints of an integer programming formulation of the problem. The solution of the relaxed problem is then used either to order the jobs in time (in one machine problems) or to assign the jobs to machines (in many machines problems). A series of ideas have been used for such a construction of a solution to the original problem including scheduling by completion times, scheduling by $\alpha$-points as well as deterministic and randomized rounding methods. As this paper focuses on PTASs design, we summarize, in Table 1, only the best known constant approximation algorithms. Clearly we omit a large body of important work on constant approximation algorithms, but the reader can acquire an accurate view of the results in this area by considering the references given in Table 1. The reader is also referred to [44] for a elegant survey on several linear programming relaxation algorithms mainly for $1 \mid$ prec $\mid \sum w_{j} C_{j}$.

Although there is practical evidence $[38,53]$ that linear programming relaxations can provide very good approximate solutions, all algorithms based on such relaxations suffer from a major drawback: the solution to a problem is compared to the solution of the relaxed one and, unfortunately, there is an integrality gap between these two solutions. Thus, comparing any solution of such an algorithm to a fractional one, inherits this gap. Hall et al. [21], Schulz and Skutella [39] and Chekuri and Motwani [10] argue on the fact that several relaxation methods for $1|p r e c| \sum w_{j} C_{j}$ can not improve on the best known 2-approximation algorithm. Moreover, Torng and Uthaisombut [51] have shown that any preemptive relaxation for $1\left|r_{j}\right| \sum C_{j}$, that uses the SRPT rule to solve the relaxed problem, can not led to an approximation factor better than $e /(e-1)$, that matches the best known factor of 1.58 [11]. It seems therefore, that the relaxation approaches can not yield a PTAS for MIN-SUM scheduling problems.

## 4. Polynomial time approximation schemes

Sahni [37] has proposed in 1976, the first FPTAS, based on dynamic programming, for the weakly NP-hard problem $P m\left|\mid \sum w_{j} C_{j}\right.$. However, no other PTAS or FPTAS was known for MIN-SUM scheduling problem before late 90's, when, Woeginger [54] proposed a FPTAS for $Q m\left|\mid \sum w_{j} C_{j}\right.$, based also on dynamic programming, and Alon et al. [4] obtained a PTAS for $P \| \sum D_{i}^{2}$ ( $D_{i}$ denotes the time by which machine $i$ completes the execution of all jobs assigned to it).

Subsequently, Skutella and Woeginger [49] realized that this last result implies also a PTAS for $P \mid w_{j} / p_{j}=$ $R \mid \sum w_{j} C_{j}$ and then in a first step they generalized this to a PTAS for $w_{j} / p_{j}$ ratios within a constant range. In a second step they obtained the first PTAS for a strongly NP-hard MIN-SUM problem $\left(P\left|\mid \sum w_{j} C_{j}\right)\right.$. Their main idea was ratio partitioning, i.e. the partitioning of the jobs into subsets such that the ratios $w_{j} / p_{j}$ of all the jobs in each subset are within a constant range. Then, using the first step, near optimum solutions are computed for all subsets. Finally, these schedules are concatenated in order of nonincreasing ratios in each machine.

Subsequently, Afrati et al. [3] used also ratio partitioning to develop a PTAS for $R m\left|\mid \sum w_{j} C_{j}\right.$. However, the concatenation of schedules that is used in ratio partitioning technique can not be applied in the presence of release dates. Thus the time partitioning technique was recalled by several researchers and it was proven powerful enough to yield PTASs for a variety of MIN-SUM scheduling problems in the presence of release dates. Several groups obtained, independently, PTASs for several variants of the average weighted completion time problem. All these results merged in to single article by eleven authors [1], where PTASs were obtained for scheduling jobs with release dates on a single machine, on identical parallel machines and on a constant number of unrelated machines in both preemptive and non-preemptive models. These results were a substantial progress in resolving the approximability question of MIN-SUM problems and it seems that the ideas proposed will influence the design of PTASs for other variants.

Indeed, based also on time partitioning technique and building on the ideas proposed in [1], Afrati et al. presented PTASs for $P 2\left|f i x_{j}\right| \sum C_{j}$ and $P m \mid f x_{j}$, pmtn| $\sum C_{j}$ in [2], and Fishkin et al. presented PTASs for $P m\left|f x_{j}, r_{j}\right| \sum w_{j} C_{j}$ and $P m\left|s i z e_{j}, r_{j}\right| \sum w_{j} C_{j}$ in [15] and $P m \mid$ set $_{j} \mid \sum w_{j} C_{j}$ in [16]. Moreover, Chekuri and Khanna using some non-trivial extensions to the ideas introduced in [1], obtained PTASs for $Q\left|r_{j}\right| \sum w_{j} C_{j}$ and $Q\left|r_{j}, p m t n\right| \sum w_{j} C_{j}$ [7].

However, it seems that it is difficult to extend the techniques for approximating the average weighted completion time in the case of average weighted flow time (recall that the flow time $F_{j}$ for each job is defined as $F_{j}=C_{j}-r_{j}$ ).

When computing optimal solutions, minimizing the average weighted completion time is equivalent to minimizing the average weighted flow time, since $\sum r_{j}$ is determined by the input. However, these two objective functions behave quite differently when we look for approximate solutions. Recently, Chekuri et al. [9] proposed initially a quasi-polynomial $2+\varepsilon$-approximation algorithm for $1\left|r_{j}, p m t n\right| \sum w_{j} F_{j}$, in the special case where the ratio of the largest job processing time over the smallest one, $P=\max _{j} p_{j} / \min _{j} p_{j}$, is polynomially bounded in $n$. After this result, Chekuri and Khanna [8] gave a quasi-PTAS for the same problem, in the case where either $P$ is polynomially bounded or the ratio of the largest job weight over the smallest one, $W=\max _{j} w_{j} / \min _{j} w_{j}$, is polynomially bounded. They also proved that this last quasi-PTAS becomes a PTAS in the cases where (i) both $P$ and $W$ are bounded, (ii) $P$ is bounded and $W$ is unrestricted and (iii) for each job its weight is the inverse of its processing time, i.e. $p_{j}=1 / w_{j}$ (also known as stretch metric).
In the third column of Table 1 we give a summary of existing (F)PTASs. We present there either the existence of a (F)PTAS or known inapproximability results in terms of either MAX SNP-hardness or existing lower bounds on the variant's approximation factor.

### 4.1. Geometric rounding and time stretching

PTASs that are based on ratio partitioning and time partitioning analyze the problem by using a combination of elementary and well understood combinatorial ingredients: partitioning, grouping, geometric rounding, enumeration and dynamic programming. The approach taken, in these PTASs, is to sequence several transformations of the input problem. Some transformations are actual changes to simplify the input, while others are applied as thought experiments to the optimum solution to prove there is a near-optimum solution with nice structure. Each transformation potentially increases the objective value by only $1+O(\varepsilon)$, that is, it produces $1+O(\varepsilon)$ loss. Besides problem-variant-specific transformations, some general transformations are used in these techniques. Such transformations are geometric rounding and time stretching.

Geometric rounding is a simplification on the given data for each job, e.g., the processing times. It creates a wellstructured set of a limited number of distinct processing times (and other data such as release dates): It rounds each processing time (and release date) to integer powers of $1+\varepsilon .{ }^{1}$ By this simplification, we degrade the cost by at most a factor of $1+\varepsilon$. To prove, we change the values in two steps. First multiply every release date and processing time by $1+\varepsilon$; this increases the objective value by $1+\varepsilon$. Then decrease each date and time to the next lower integer power of $1+\varepsilon$ (which is still greater than the original value). This can only improve things for the problems considered in this paper.

The second simplification, time stretching, creates idle time gaps evenly spread along the schedule. These gaps will be used conveniently in later transformations to accommodate jobs that we are moving around in order to prove that there is a near-optimum schedule with nice structure. ${ }^{2}$ Often, we will use time stretching to add an idle amount of $\varepsilon p_{j}$ time units before every job $j$. This will increase each completion time (and hence their sum) by a factor of $1+\varepsilon$. According to this last transformation, we may also assume that the starting time of each job $j$ is $S_{j} \geqslant \varepsilon p_{j}$ : If job $j$ completed at time $t>p_{j}$ then it now completes at time $(1+\varepsilon) t$ and therefore does not start until time $\varepsilon t \geqslant \varepsilon p_{j}$.

## 5. Ratio partitioning

In this section, we want to find a PTAS for the problem $R 2 \| \sum w_{j} C_{j}$. First, we observe that we only need to decide on which machine each job will be executed. This is so, because, if we know that, then the optimum schedule on each machine is given by Smith's rule (see Section 2.2.1). The structure of this section is as follows. Before we present the algorithm, we show that certain simplifying assumptions can be done to the problem without affecting its cost very much. In fact, it is easy to see that these assumptions apply to a more general variant, i.e., in the case we have any constant number of machines.

[^2]We make the following simplifying assumptions:
(a) For a job with its processing times far apart, we can immediately decide on which machine the job will be executed with negligible loss.
(b) It is easy to see that we can view the calculation of the objective function as the sum of products, each product being essentially the contribution to the cost of the interaction between pairs of jobs. Then, we can observe that pairs of jobs with very different ratios do not contribute much to the cost function, hence such contributions can be equated to zero with negligible loss.
(c) Summing up assumptions (a) and (b) and adding geometric rounding and grouping, we observe that only a constant number of pairs of jobs affect each other, namely the ones with comparable ratios. This leads to a dynamic programming algorithm.

Before we move on with discussing the above assumptions in quantitative terms and in order to facilitate this discussion we define a partitioning of the range of ratios into disjoint windows such that the $i^{\text {th }}$ window consists of ratios in the range $F_{i}=\left(a_{\text {max }}^{i} R, a^{i-1} R_{\text {max }}\right]$, where $R_{\text {max }}=\max _{i, j}\left\{w_{j} / p_{j}^{(i)}\right\}$ and $a=\varepsilon^{4}$. For the same reason, we define a job-type $T_{R, R^{\prime}}$ as the set of jobs having the same pair of ratios, i.e. $T_{R, R^{\prime}}=\left\{j \mid R_{j}^{(1)}=R\right.$ and $\left.R_{j}^{(2)}=R^{\prime}\right\}$, where $R_{j}^{(i)}=w_{j} / p_{j}^{(i)}$.

Now, we can repeat our three assumptions in a bit more quantitative (yet not formal) terms:
(a) We can think of each job as having its two ratios either in the same window or in adjacent windows.
(b) "Very different" job types do not affect each other.
(c) We can bound the number of jobs within each job-type by a constant number.

In the following three subsections we state and prove formally these three simplifying assumptions.

### 5.1. Ratios in adjacent windows

We prove that for each job, either we can tell in advance in which machine it will be scheduled (we say that it is decided) or else its two ratios do not differ much. If the processing times of a job are very different on the two machines, then we can directly decide to schedule it on the machine on which it has the shortest processing time. In quantitative terms: we can assume that all jobs such that $p_{j}^{(1)}<\varepsilon p_{j}^{(2)}$ are scheduled on $M_{1}$ (we say that this job is $M_{1}$-decided), and that all jobs such that $p_{j}^{(2)}<\varepsilon p_{j}^{(1)}$ are scheduled on $M_{2}$ (we say that this job is $M_{2}$-decided). To prove, we show that by moving all such jobs to the machine with the small processing time, the cost does not increase much: we move each such job $j$ in the other machine so that it starts just before the earliest job which completes at time $>C_{j}$ (the completion time of the moved job in the original schedule). This affects the total cost by increasing the completion time of job $j$ and by delaying the jobs after $j$ in the machine $M_{1}$ (suppose we moved the job to $M_{1}$ ). However, the new completion time of job $j$ is at most $C_{j}+p_{j}^{(1)}<C_{j}+\varepsilon p_{j}^{(2)}<C_{j}(1+\varepsilon)$. The other jobs affected are the jobs in machine $M_{1}$ which are delayed. Each such job $k$ is delayed by at most $\varepsilon$ times the sum of $M_{2}$-processing times of moved jobs which completed before time $C_{k}$ in $M_{2}$; but this is at most $\varepsilon$ times $C_{k}$. Thus, in this case, we can put $p_{j}^{(2)}=\infty$ or $p_{j}^{(1)}=\infty$ accordingly. Moreover, for each undecided job we now know that $p_{j}^{(1)}>\varepsilon p_{j}^{(2)}$ and $p_{j}^{(2)}>\varepsilon p_{j}^{(1)}$, that is $\varepsilon<R_{j}^{(1)} / R_{j}^{(2)}<1 / \varepsilon$. Hence, each job is either decided or it has its two ratios either in the same window or in adjacent windows.

### 5.2. Job types not affecting each other

We want to prove that "very different" job types do not affect each other. To state formally, we rewrite the cost function as

$$
\sum_{j, k \text { on } M_{1}} \mathscr{M}_{1}[j, k]+\sum_{j, k \text { on } M_{2}} \mathscr{M}_{2}[j, k],
$$

where

$$
\forall j, k \in J, \quad \mathscr{M}_{i}[j, k]= \begin{cases}p_{k}^{(i)} w_{j} & \text { if } j=k, \\ \frac{1}{2} p_{k}^{(i)} w_{j} & \text { if } j \neq k \text { and } \frac{w_{k}}{p_{k}^{(i)}}=\frac{w_{j}}{p_{j}^{(i)}}, \\ p_{k}^{(i)} w_{j} & \text { if } \frac{w_{k}}{p_{k}^{(i)}}>\frac{w_{j}}{p_{j}^{(i)}}, \\ 0 & \text { otherwise. }\end{cases}
$$

Notice that an entry $\mathscr{M}_{i}[j, k]$ represents the contribution to the cost function of job $j$, due to job $k$.
Using this formulation of the cost function, we can prove that if the ratios of two jobs are very different, then we can neglect their interaction:
(i) For every pair of jobs $\{j, k\}$ such that $R_{j}^{(i)}<\varepsilon^{2} R_{k}^{(i)}$, we can replace $\mathscr{M}_{i}[j, k]$ by 0 .
(ii) For $i=1,2$, and for every pair of jobs $\{j, k\}$ such that $j$ and $k$ are either $M_{i}$-decided or undecided, and such that $R_{j}^{(i)}<\varepsilon^{4} R_{k}^{(i)}$, we can replace both $\mathscr{M}_{1}[j, k]$ and $\mathscr{M}_{2}[j, k]$ by 0.

Proof of (i). We prove this in two steps: first for each $k$ on $M_{1}$, we look at the jobs $j$ on $M_{1}$ such that $R_{j}^{(1)}<\varepsilon^{2} R_{k}^{(1)}$, and whose completion times satisfy $C_{k}<\varepsilon C_{j}$. The presence of $k$ before such a $j$ has only a marginal effect on $j$ 's completion time (easy to prove). Second, we look at the pairs $\{j, k\}$ which are scheduled on $M_{1}$, such that $R_{j}^{(1)}<\varepsilon^{2} R_{k}^{(1)}$, but whose completion times satisfy $C_{j} \leqslant C_{k} / \varepsilon$. The contribution to the cost function of those pairs is very little as compared to $w_{k} C_{k}$ :

$$
\begin{aligned}
\sum_{\substack{j \text { on } M_{1} \\
C_{j} \leqslant C_{k} / \varepsilon}} w_{j} p_{k}^{(1)} & =\sum_{\substack{j \text { on } M_{1} / \varepsilon \\
C_{j} \leqslant C_{k} / \varepsilon}} r_{j}^{(1)} p_{j}^{(1)} p_{k}^{(1)}<\varepsilon^{2} \sum_{\substack{j \text { on } M_{1} \\
C_{j} \leqslant C_{k} / \varepsilon}} w_{k} p_{j}^{(1)} \\
& =\varepsilon^{2} w_{k} \sum_{\substack{j \text { on } M_{1} \\
C_{j} \leqslant C_{k} / \varepsilon}} p_{j}^{(1)} \leqslant \varepsilon^{2} w_{k} \max _{\substack{j \text { on } M_{1} \\
C_{j} \leqslant C_{k} / \varepsilon}} C_{j} \leqslant \varepsilon^{2} w_{k} C_{k} / \varepsilon=\varepsilon w_{k} C_{k},
\end{aligned}
$$

Proof of (ii). Consider the case $i=1$. Because $R_{j}^{(1)}<\varepsilon^{2} R_{k}^{(1)}$, we can replace $\mathscr{M}_{1}[j, k]$ by 0 -according to (i) above which we just proved. If either job is $M_{1}$-decided, then it will never be placed on $M_{2}$ and so we can replace $\mathscr{M}_{2}[j, k]$ by 0 . If both are undecided, then we have: $p_{j}^{(2)}>\varepsilon p_{j}^{(1)}$ and $p_{k}^{(2)}<p_{k}^{(1)} / \varepsilon$. Thus: $w_{j} / p_{j}^{(2)}<(1 / \varepsilon) w_{j} / p_{j}^{(1)}<\left(\varepsilon^{4} / \varepsilon\right) w_{k} / p_{k}^{(1)}<\left(\varepsilon^{4} / \varepsilon\right)$ $(1 / \varepsilon) w_{k} / p_{k}^{(2)}=\varepsilon^{2}\left(w_{k} / p_{k}^{(2)}\right)$. Thus the condition in (i) is satisfied, hence, we can replace $\mathscr{M}_{2}[j, k]$ by 0 .

### 5.3. Constant number of jobs

We can bound the number of jobs within each job-type by a constant number. Consider a job-type $T_{R, R^{\prime}}$ and the sum of the weights, $W_{R, R^{\prime}}$, of jobs in $T_{R, R^{\prime}}$. We group small jobs together to build larger compound jobs. Thus, we can assume that every job of a job-type has weight at least $\varepsilon^{2} W_{R, R^{\prime}}$, and hence each job-type has at most $1 / \varepsilon^{2}=O(1)$ elements. More specifically, we group greedily so that the sum of weights of the tiny jobs in each group (which now represents the weight of the compound job) is between $\varepsilon^{2} W_{R, R^{\prime}}$ and $2 \varepsilon^{2} W_{R, R^{\prime}}$. There are two points to discuss:
(i) The cost does not change much by this grouping. For each group $k$ (in machine $i$ with ratio $R$ say), the contribution to the cost function before the grouping was $\sum_{m, n}$ jobs in group $k p_{m}^{(i)} p_{n}^{(i)}$. This quantity, though, is bounded on both sides by $R\left(\sum_{n} \text { job in group } k p_{n}^{(i)}\right)^{2}$ and $R \frac{1}{2}\left(\sum_{n} \text { job in group } k p_{n}^{(i)}\right)^{2}$ (upper and lower bound respectively). Hence it is at most $(4 / R) \varepsilon^{4} W_{R, R^{\prime}}^{2}$. Similarly the jobs in this job type contribute to the total cost by a quantity which is at least $(1 / 2 R) W_{R, R^{\prime}}^{2}$. There are at most $1 / \varepsilon^{2}$ compound jobs, hence the total shift from the original cost is at most $\left(4 / \varepsilon^{2} R\right) \varepsilon^{4} W_{R, R^{\prime}}^{2}$ which is less than $\varepsilon(1 / 2 R) W_{R, R^{\prime}}^{2}$.
(ii) Clearly a schedule that uses the compound jobs results in a cruder fractioning of the jobs in the job type among the machines. To take care of that we stretch time by $1+\varepsilon$ and this stretching is enough to accommodate the compound jobs.

### 5.4. Algorithm for $R 2 \| \sum w_{j} C_{j}$

We first simplify the input of the problem by applying geometric rounding on the parameters defining the jobs. Then, we identify the jobs which are $M_{1}$-decided or $M_{2}$-decided. We replace all irrelevant processing times (i.e. $p_{j}^{(2)}$ if $j$ is $M_{1}$-decided and $p_{j}^{(1)}$ if $j$ is $M_{2}$-decided) by $\infty$, which means that the corresponding ratio becomes equal to 0 . This leaves us with undecided jobs that have their two ratios either in the same window or in adjacent windows.
Then we do all the simplifications of the previous subsection, namely calculating first the $\mathscr{M}_{i}[j, k]$ and then putting accordingly some of them equal to 0 .

Note that, the set of undecided jobs having at least one ratio in a specific window has size $O\left(\log ^{2}(1 / \varepsilon) / \varepsilon^{2}\right)$ : Roughly, because of geometric rounding, we have only a constant number of different ratios within a window and, because undecided jobs have their ratios either in the same window or in adjacent windows, there is only a constant number of job types that may contain a job of a particular ratio in one of the machines. Moreover, there is a constant number of jobs within each job type.

Now, in deciding where to put optimally the undecided jobs, we have to calculate the cost of the schedule. In this calculation, as we proved in Section 5.2, we sum up the contribution to the cost of all pairs of jobs and, moreover, we can neglect with negligible loss the contribution of pairs with very different ratios. This means, in quantitative terms that for such a pair of jobs $j, k$ we set their contribution $\mathscr{M}_{i}[j, k]$ equal to zero.

Thus, summing up the above analysis, we have reduced the problem to a problem of scheduling jobs in two machines under the following (convenient) constraints: (a) Each job type has the two ratios either in the same window or in adjacent windows and (b) Job types affect each other only in the stretch of two windows and (c) there is a constant number of undecided jobs with at least one of their ratios in a specific window. An immediate consequence of that is dynamic programming with respect to the windows of ratios. In each stage $i$ of the dynamic programming, we have fixed the schedule for jobs with their both ratios in windows $F_{1}, \ldots, F_{i}$ and keep all possible schedules of jobs with at least one of their ratios in window $F_{i}$. Thus, each stage runs in $O(1)$ time.

## 6. Time partitioning

In this section we want to find PTASs for the problems, $1\left|r_{j}\right| \sum C_{j}$ and $P 2\left|f i x_{j}\right| \sum C_{j}$.
The complication in the first problem is that we have to deal with release dates too. In the absence of release dates, the problem has a simple polynomial algorithm (the algorithm that schedules according to the SPT rule, see Section 2.2.1). Also, the variant with release dates and preemption has a polynomial algorithm which solves it optimally. It is again a simple algorithm which, now, schedules according to the shortest processing remaining time first (SPRT rule). The PTAS that we will explain here is using this algorithm. It finds first a preemptive schedule, and then argues that we can move jobs around so that most of them can be completed in a non preemptive manner with negligible added cost.

The complication in the second problem is that we have multiprocessor jobs. In particular, the variant that we consider here deals with dedicated jobs, i.e., each job $j$ requires for its execution the simultaneous availability of a prespecified subset of machines $\tau_{j}=\left\{M_{1}, \ldots, M_{m}\right\}$ for $p_{j}$ time units. The set $\tau_{j}$ is called the type of job $j$. We restrict attention here to the case with two machines. The methods and techniques though extend easily to the case of any fixed number of machines. For this problem, we have two kinds of monoprocessor jobs, the 1 -jobs and the 2 -jobs dedicated to run on machine $M_{1}$ and $M_{2}$, respectively. Biprocessor 12-jobs are dedicated to both machines. Again the variant of the problem where preemption is allowed has a polynomial algorithm that solves it optimally [6].

Now we explain time partitioning and in the next subsection, we show how we may assume some structure in the near-optimal schedule. Then, we discuss the algorithms for each problem separately.

### 6.1. Simple properties of time partitioning

We partition the time axis in intervals as follows. For an arbitrary integer $x$, we define $R_{x}=(1+\varepsilon)^{x}$. We partition the time interval $(0, \infty)$ into disjoint intervals $I_{x}=\left[R_{x}, R_{x+1}\right)$. We will use $I_{x}$ to refer to both the interval and the size $\left(R_{x+1}-R_{x}\right)$ of the interval. We will often use the fact that $I_{x}=\varepsilon R_{x}$, i.e., the length of an interval is $\varepsilon$ times its start time. We consider an optimum schedule and focus on the schedule of one machine. The reason this time partitioning
is useful is that each interval can be used to accommodate jobs of relatively small size and thus we can assume that, in a near-optimal schedule, finishing up jobs on a preemptive schedule comes at negligible cost. To argue that intervals accommodate small jobs, we show that moving around jobs (from smaller intervals to intervals comparable to their size), does not degrade the cost very much. In a way, this generalizes the intuition discussed in Section 2.2.3.

Now, we make it formal. The following are easy to prove useful facts:
(a) By time stretching we can create, in each interval an idle gap of size $\varepsilon I_{x}$.
(b) Moving a job $j$ inside the interval in which it runs produces a $1+O(\varepsilon)$ loss because it will only increase its completion time by at most $I_{x}$ which is less than $\varepsilon R_{x+1}$, consequently less than $\varepsilon C_{j}$.
(c) A job can not be "arbitrarily large", i.e., it crosses a constant number of intervals. In quantitative terms, we argue as follows. In the worst case, a job starts at time $\varepsilon p_{j}$ and completes at time $\varepsilon p_{j}+p_{j}$, hence, it crosses at most $s=\left\lceil\log _{1+\varepsilon}\left(\left(\varepsilon p_{j}+p_{j}\right) / \varepsilon p_{j}\right)\right\rceil=\left\lceil\log _{1+\varepsilon}(1+1 / \varepsilon)\right\rceil$ intervals.
(d) If a job $j$ crosses several intervals, we know that it crosses at most $s$ intervals, and then we can accumulate idle time for all $s$ intervals in the beginning of job $j$, and we know that the relative size of the 1 st interval to the size of the $s$-th interval is $\geqslant I_{x} /\left(I_{x+s}\right)=1 /(1+\varepsilon)^{s-1}=\varepsilon$.

### 6.2. Large and small jobs

In many cases, jobs that are much smaller than the interval in which they run are essentially negligible and easy to deal with. The difficulty comes from jobs that are large-taking up a substantial portion of the interval. ${ }^{3}$

We assume, here, that small jobs are defined to be those with $p_{j}<\varepsilon I_{x}$, where $I_{x}$ is the interval where job $j$ runs. Jobs that do not have this property are called large. The following are to prove facts:
(a) We may restrict attention to schedules in which no small job crosses an interval: By time stretching, add in each interval a gap of $\varepsilon I_{x}$ and finish the single small job that may be crossing an interval.
(b) There is a constant number of large jobs in an interval, namely at most $1 / \varepsilon$.

Interestingly, we can almost get rid altogether of large jobs in all intervals, except a constant number of them. I.e., we can put structure in a near-optimal schedule so that all jobs are small in the interval they run except a constant number of them in the entire schedule, which we call huge jobs. Thus, the huge jobs are large jobs that we can not move in larger intervals without a considerable degradation of the cost. We can enforce such a structure by moving most large jobs in larger intervals without much degrading the quality of the schedule. Thus, we end up with an overall constant number of huge jobs. As expected the huge jobs are the ones whose starting time $S_{j}$ is very close to the optimum cost OPT:

Lemma 1. With a $1+O(\varepsilon)$ loss, we assume
(i) For each job j, $S_{j} \geqslant \min \left\{\frac{p_{j}}{\varepsilon^{2}}, \varepsilon^{7} O P T\right\}$.
(ii) All jobs are small in the intervals they run except at most $1 / \varepsilon^{7}$.

Proof. The proof of (ii) follows from (i): Note that $S_{j} \geqslant p_{j} / \varepsilon^{2}$ means that job $j$ is small in the interval it runs. Also, all jobs starting after time $\varepsilon^{7} O P T$ are at most $1 / \varepsilon^{7}$. The small jobs trivially satisfy this condition in (i). We move around large jobs in larger intervals so that they are now small in the interval that they run. We do that only for large jobs that complete before $\varepsilon^{7} O P T$.
We move a job that completes before time $\left(1+\frac{1}{\varepsilon^{2}}\right) p_{j}$ in the first gap after time $t=C_{j} / \varepsilon^{4}$. We have to worry about three considerations:
(a) There is space large enough to accommodate all jobs that are landed on a particular gap. This is so because the gap at time $t$ is equal to $\varepsilon^{2} t$, that is at least equal to $C_{j}$ and hence it accommodate all jobs which complete before time $C_{j}$.

[^3](b) There is not some hugely long crossing job in this interval. This is guaranteed by the fact that any crossing job may cross at most $s$ intervals. Thus, we put the moved job in the beginning of the crossing job and still it is in an interval where it is considered small. This is so because the intervals that a job crosses differ in size by a factor at most $1 / \varepsilon$.
(c) The added cost is not too much: We need to bound the added cost of the large jobs we moved forward. The last interval from which we advance jobs ends at time $t=\varepsilon^{7} O P T$. Thus the total completion time of the advanced jobs is $\left.\sum_{R_{x}<t}(1 / \varepsilon)\left((1+\varepsilon) R_{x} / \varepsilon^{4}\right)(\leqslant) t / \varepsilon^{5}\right) \sum_{i \geqslant 0} 1 /(1+\varepsilon)^{i}=\left(t / \varepsilon^{5}\right)\left((1+\varepsilon)^{2} / \varepsilon\right)=\varepsilon$ OPT $(1+\varepsilon)^{2} \leqslant 2 \varepsilon$ OPT as desired.

### 6.3. Algorithm for $1\left|r_{j}\right| \sum C_{j}$

We first simplify the input of the problem by applying geometric rounding on the parameters. Thus, jobs are released only in the end of intervals. Now, we use the simplifications that, as we proved in the previous subsections of this section, do not degrade much the quality of the schedule. Before we present the algorithm that solves the problem in the general case we treat an easy subcase. Suppose that, in the near optimal schedule of the preemptive problem, all jobs are small in the interval they run. Then the following simple algorithm finds a near optimal solution: Step 1: We set release dates equal to $\max \left\{r_{j}, p_{j} / \varepsilon^{2}\right\}$. According to Lemma 1 , this does not change the feasibility of a nearly optimum schedule. Step 2: We use SPRT rule to obtain an optimum preemptive schedule and then stretch each interval by $\varepsilon I_{x}$ and use the extra space to accommodate the tails of the preempted jobs. Step 2, however, is equivalent to running SPT rule.

Now in the general case, we also have the huge jobs to accommodate. I.e., the optimum schedule may require some jobs to run in intervals such that they are large. By Lemma 1, however, there is still a nearly optimum solution with only a constant number of large jobs. Hence we find an optimum schedule of them by exhaustive enumeration and schedule the small jobs around them as we explained above.

### 6.4. Algorithm for $P 2\left|f x_{j}\right| \sum C_{j}$

For this case, we need some more discussion to explain how we deal with multiprocessor jobs. We use again a relaxation to the preemptive case. The analysis goes through for any fixed number of machines $M$, only that, for $M>2$ the preemptive case is not polynomial and is solved by a PTAS too.

### 6.4.1. Parallel running jobs have comparable processing times

Besides geometric rounding, we need some more transformations. We begin with the following lemma which states that jobs scheduled to run in parallel have comparable processing times.
We first state a few useful facts:
(a) If $p_{\max }$ is the maximum processing time of a set of jobs and $\ell$ and $C$ is the length and the cost respectively of a schedule of this set of jobs, then, $\ell<2 \sqrt{p_{\max } C}$. At least $\ell / 2 p_{\max }$ jobs will be executed after time $\ell / 2$, hence the cost is at least: $C \geqslant\left(\ell / 2 p_{\max }\right) \ell / 2$, hence the inequality.
(b) Suppose each processing time is $<\varepsilon^{10}$, then the makespan is $\ell<2 \sqrt{p_{\max } C}<2 \sqrt{\varepsilon^{10} C^{2}}$, hence $\ell<2 \varepsilon^{5} C$.

Lemma 2. With a $1+O(\varepsilon)$ loss, we never have two jobs scheduled in parallel whose processing times differ by a factor greater than $1 / \varepsilon^{5}$.

Proof. Let $j$ be a job executed w.l.o.g. on machine $M_{1}$, and let $A$ be the set of jobs scheduled in parallel with $j$ on machine $M_{2}$ with processing times $<\left(1 / \varepsilon^{5}\right) p_{j}$. Recall that, since the single-machine-jobs on each machine are scheduled in the order of increasing processing times, all jobs in $A$ run in a single consecutively.

The intuition of this proof is the following: We have two cases. Case (i): All jobs in $A$ occupy when they run time less than $\varepsilon p_{j}$. Then, by time stretching we move the job $j$ by at most $\varepsilon p_{j}$ and the additional cost is small compared to the processing time $p_{j}$ of job $j$. Case (ii): All jobs in $A$ occupy when they run more than $\varepsilon p_{j}$. Then, the number of jobs in $A$ is comparatively large, hence we move the job $j$ in a larger interval and, by time stretching, the additional cost is small compared to the sum of completion times of jobs in $A$. We argue now quantitatively on the two cases:

Case (i): $\sum_{i \in A} p_{i}<\varepsilon p_{j}$. We use time stretching to move starting time of $j$ to $S_{j}+\varepsilon p_{j}$, thus jobs in $A$ and job $j$ do not run in parallel any more.

Case (ii): $\sum_{i \in A} p_{i} \geqslant \varepsilon p_{j}$. Put the job $j$ so that it completes at time $C_{j} / \varepsilon^{2}$. Let $S_{j}$ be the starting time of job $j$ in the initial schedule. Since for every $i \in A, p_{i}<\varepsilon^{5} p_{j}$, we get that at least $1 / 2 \varepsilon^{4}$ jobs in $A$ complete in the timeinterval $\left[S_{j}+\varepsilon p_{j} / 2, S_{j}+\varepsilon p_{j}\right]$. Then $\sum_{i \in A} C_{i}>\left(S_{j}+\varepsilon p_{j} / 2\right)\left(1 / 2 \varepsilon^{4}\right)>(\varepsilon / 2)\left(1 / 2 \varepsilon^{4}\right)\left(S_{j}+p_{j}\right)=\left(1 / 4 \varepsilon^{3}\right) C_{j}$. Thus, $\left(C_{j} / \varepsilon^{2}\right)<4 \varepsilon \sum_{i \in A} C_{i}$. Summing over all jobs $j$, we get an increase of at most $4 \varepsilon O P T$.

### 6.4.2. Gap in processing times

Suppose that there is a gap in the values of the processing times of the jobs in the sense that we can partition the set of jobs into "long" and "short" jobs so that the processing times of all long jobs are much larger than any processing time of a small job. Then the following lemma states that all short jobs are scheduled before any long job is scheduled.

Lemma 3. Suppose that the set of jobs $\mathscr{T}$ can be partitioned into subsets $L$ and $S$ such that $\max _{j \in S} p_{j}<\varepsilon^{5} \min _{j \in L} p_{j}$. Then, all jobs in $S$ are scheduled before any job in $L$ is scheduled with $1+\varepsilon$ loss.

Proof. Observe that, because of Lemma 2 above, we can view a near-optimal schedule as a series of time intervals, each time interval accommodating either only jobs in $L$ or only jobs in $S$. Suppose there are two consecutive time intervals so that a subset $L^{\prime}$ of $L$ jobs is scheduled before a subset $S^{\prime}$ of $S$. If we swap the schedules in those time intervals so that $S^{\prime}$ is scheduled before $L^{\prime}$, then we get a better schedule. We compute the change in cost. Let $\mathscr{S}$ and $\mathscr{L}$ are the length of the time interval in which the jobs in $S^{\prime}$ and $L^{\prime}$, respectively, are scheduled. The jobs of $L^{\prime}$ are delayed by $\mathscr{S}$ while the jobs of $S^{\prime}$ are moved up by $\mathscr{L}$. Thus the change of the cost is

$$
\mathscr{S}\left|L^{\prime}\right|-\mathscr{L}\left|S^{\prime}\right| \leqslant\left(\frac{2}{\min _{j \in L} p_{j}}-\frac{1}{\max _{j \in S} p_{j}}\right) \mathscr{L} \mathscr{S} \leqslant\left(2-\frac{\min _{j \in L} p_{j}}{\max _{j \in S} p_{j}}\right) \frac{\mathscr{L} \mathscr{S}}{\min _{j \in L} p_{j}} .
$$

By the hypothesis we have that $\min _{j \in L} p_{j} / \max _{j \in S} p_{j}>1 / \varepsilon^{5}$, hence the upper bound on the change of cost is a negative number for $\varepsilon<\frac{1}{2}$.

However this lemma cannot be used unless there is such a gap. It turns out that there is an "almost gap". Namely, a separation result allows for partitioning the jobs into "long" jobs and "short" jobs with a few (negligible) "medium" jobs in between. $U$ denotes the upper bound to the optimal cost obtained by processing all jobs sequentially. Note that this upper bound is within a factor of 2 of the optimal.

Definition. Let $L_{i}$ denote the set of jobs with processing time $p_{j} \geqslant \varepsilon^{5 i+5} U, M_{i}$ denote the set of jobs $j$ with processing time $\varepsilon^{5 i+10} U \leqslant p_{j}<\varepsilon^{5 i+5} U$, and $S_{i}$ denote the remaining jobs.

Lemma 4. If $L_{1} \neq \emptyset$, then there is some $i<\log _{1+\varepsilon} \frac{1}{\varepsilon^{10}}$ such that $O P T\left(M_{i} \cup L_{i}\right) \leqslant\left(1+\varepsilon^{2}\right) O P T\left(L_{i}\right)$. We call this $i$ the separation index.

Proof. The proof is a simple algebraic manipulation. Observe that $L_{i}=L_{1} \cup M_{1} \cup M_{2} \cup \ldots \cup M_{i-1}$. Taking the inequality $O P T\left(L_{1}\right)>\varepsilon^{10} O P T$, and $i$ inequalities, one for each $i: O P T\left(M_{i} \cup L_{i}\right)>\left(1+\varepsilon^{2}\right) O P T\left(L_{i}\right)$ or equivalently $O P T\left(L_{1} \cup M_{i} \cup M_{1} \cup M_{2} \cup \cdots \cup M_{i-1}\right)>\left(1+\varepsilon^{2}\right) O P T\left(L_{1} \cup M_{1} \cup M_{2} \cup \cdots \cup M_{i-1}\right)$ and multiplying the RHS parts and the LHS parts yields the inequality: $O P T>O P T\left(L_{1} \cup M_{1} \cup \cdots \cup M_{i}\right)>\left(1+\varepsilon^{2}\right)^{i} \varepsilon^{10} O P T$, i.e. $\left(1+\varepsilon^{2}\right)^{i} \varepsilon^{10}<1$. Consequently, $i<\log _{1+\varepsilon^{2}} \frac{1}{\varepsilon^{10}}$.

Combining the results in Lemmas 3 and 4, we get the following:
Lemma 5. Let $i$ be the separation index. Then, with a $1+\varepsilon$ loss, we schedule all jobs in $S_{i}$ before all jobs in $L_{i} \cup M_{i}$.
Proof. We will show that the cost does not increase much. By Lemma 3, we know that there is a schedule with a $1+\varepsilon$ loss from the optimal, which schedules first the jobs in $S_{i}$ and then the jobs in $L_{i}$. The cost of this schedule is $C\left(S_{i} \cup L_{i}\right)=O P T\left(S_{i}\right)+O P T\left(L_{i}\right)+M^{S_{i}}\left|L_{i}\right|$ where $M^{S_{i}}$ is the maximum makespan of the optimum schedule in $S_{i}$.

The cost of a schedule which schedules first $S_{i}$ and then $M \cup L_{i}$ is $O P T\left(S_{i}\right)+O P T\left(M_{i} \cup L_{i}\right)+M^{S_{i}}\left|M_{i} \cup L_{i}\right|$. Since, we already know that $O P T\left(M_{i} \cup L_{i}\right)<(1+\varepsilon) O P T\left(L_{i}\right)$ (by Lemma 4), we need to bound $M^{S_{i}}\left|M_{i}\right|$.

Let $p_{\min }^{L_{i}}$ be the shortest processing time of a job in $L_{i}$, then:

$$
\frac{\left|L_{i}\right|^{2}}{4} p_{\max }^{S_{i}}<\frac{\left|L_{i}\right|^{2}}{4} p_{\min }^{L_{i}}<O P T\left(L_{i}\right)<\varepsilon^{2} O P T\left(L_{i}\right)
$$

Hence $\left|L_{i}\right|<2 \varepsilon \sqrt{\frac{O P T\left(L_{i}\right)}{p_{\text {max }}}}$. From the observation in the beginning of this subsection $M^{S_{i}}<2 \sqrt{p_{\max }^{S_{i}} O P T\left(S_{i}\right)}$, and thus $M^{S_{i}}\left|L_{i}\right|$ is at most $2 \varepsilon O P T$.

The above transformations together with a polynomial algorithm for the preemptive variant [2] yield a PTAS for this problem. We develop the algorithm in two stages. First suppose there are no jobs with processing time $>\varepsilon^{10} O P T$. Then we get the algorithm:
(1) Solve the preemptive problem with at most $1+\varepsilon$ loss.
(2) Reorder jobs in each type by non-decreasing processing time.
(3) Reorder to obtain a schedule with at most one preemption per interval.
(4) Move large uniprocessor jobs in long intervals so that starting time for uniprocessor jobs is greater than $\left(1 / \varepsilon^{2}\right) p_{j}$, according to Lemma 1.
(5) Consider each preempted job, $j$, (it is always a single-machine job) and finish it at the time of preemption.

The analysis of this algorithm is straightforward from the above lemmas.
Now, the algorithm for the general case is:
(1) For every $i<\log _{1+\varepsilon} \frac{1}{\varepsilon_{10}^{10}}$, partition the jobs into $L_{i}, M_{i}, S_{i}$.
(2) Construct a non-preemptive schedule of $S_{i}$ as above.
(3) Construct an optimal non-preemptive schedule of $L_{i} \cup M_{i}$ by exhaustive search.
(4) Concatenate the schedule of $S_{i}$ and the schedule of $L_{i} \cup M_{i}$.
(5) Choose the best schedule over all choices of $i$.

## 7. Open questions

The recent activity on MIN-SUM scheduling problems has led to resolving many of the approximability questions arising in this area as it is shown in Table 1. Several open questions can be picked up by looking at this table. Schuurman and Woeginger in [42] provide also an excellent listing of ten open problems in scheduling theory, including MIN-SUM scheduling problems. In [42], they also discuss related MIN-SUM scheduling problems that we do not address here such as shop scheduling problems and scheduling problems with communication delays.
However, we believe that some of the most interesting open questions can be classified into three directions.
(i) The variants with precedence constraints are still far from being resolved. Any $\rho$-approximation algorithm, with $\rho<2$ or any negative result for $1 \mid$ prec $\mid \sum w_{j} C_{j}$ will be of great interest. Note that at least four different 2-approximation algorithms are known (see Table 1) for this variant. Moreover, Woeginger [55], gave a proof that eight special cases of $1 \mid$ prec $\mid \sum w_{j} C_{j}$ (including $1 \mid$ prec $\mid \sum C_{j}$ ) all have the same approximation threshold. Thus, what we can, possibly, expect is a negative result like the following.

Conjecture 1. There is no $(2-\varepsilon)$-approximation algorithm for $1 \mid$ prec $\mid \sum C_{j}$.
(ii) The unrelated machines case, with the number of machines as part of the problem's instance, is also of interest. We know that $R \| \sum w_{j} C_{j}$ as well as $R\left|r_{j}\right| \sum C_{j}$ (and hence $R\left|r_{j}\right| \sum w_{j} C_{j}$ ) are MAXSNP-hard [23] and that they can be approximated within a factor of $\frac{3}{2}[43,46,48]$ and $2[47,48]$, respectively. We also know that their preemptive variants, i.e. $R|p m t n| \sum w_{j} C_{j}$ and $R\left|r_{j}, p m t n\right| \sum w_{j} C_{j}$, can be approximated within a factor of $2[47,48]$ and $2+\varepsilon$ [35] respectively. However, the existence of an approximation threshold (for the non-preemptive variants) and a PTAS
(for the preemptive variants) are two major open questions. Last but not least note that the complexity of $R|p m n t| \sum C_{j}$ was an longstanding open question and recently it was shown to be strongly NP-hard [45]. However, the existence of an approximation result better than the one to its weighted variant is unknown. It follows, therefore, that there is enough room for improvements here and that any conjecture will be very risky.
(iii) Neither PTASs nor constant approximation algorithms are known for the case with objective function the total (weighted) flow time. Such a result is not however expected for the non preemptive variants due to known nonapproximability results [25,26]. Recent work in [9] and [8] (see the discussion in Section 3) for $1\left|r_{j}, p m t n\right| \sum w_{j} F_{j}$ provides a strong evidence that the following conjecture holds.

Conjecture 2. There is a PTAS for $1\left|r_{j}, \operatorname{pmtn}\right| \sum w_{j} F_{j}$.
For the parallel machines preemptive unweighted variant $P\left|r_{j}, p m t n\right| \sum F_{j}$ an $O(\log \min \{n / m, \log P\})$ -approximation algorithm is known [26], whereas no negative result has been shown (recall that $P$ refers to the ratio of the largest job processing time over the smallest one, i.e. $P=\max _{j} p_{j} / \min _{j} p_{j}$ ). It would be interesting to have either better approximation factor or a negative result for this variant or even for $P 2\left|r_{j}, p m t n\right| \sum F_{j}$.

## 8. Conclusion

In this paper, we have discussed approximation algorithms for scheduling problems. We have presented a brief survey on successful methods and techniques used for deriving constant ratio approximation algorithms. However, for a more detailed exposition on this subject and especially on methods that use relaxation techniques on integer programming formulations of the problem, the reader is asked to refer to surveys in the literature. We have focused in Polynomial Time Approximation Schemes and we have presented an extended formal exposition of algorithms in the literature. We presented PTAS algorithms for three problems: $R 2 \| \sum w_{j} C_{j}, 1\left|r_{j}\right| \sum C_{j}$, and $P 2\left|f i x_{j}\right| \sum C_{j}$. Finally note that it was not our goal here to discuss variants of shop scheduling problem.

[^1]:    ${ }^{\text {a }}$ Quasi-polynomial algorithm for poly-bounded $P$.
    ${ }^{\mathrm{b}}$ For poly-bounded $P$ or $W$.

[^2]:    ${ }^{1}$ In the rest of the paper, as we are only discussing PTASs, we use the given approximation factor $\varepsilon$ as one of the given parameters of the problem.
    ${ }^{2}$ Recall also the discussion in Section 2.2.3.

[^3]:    ${ }^{3}$ Small jobs are a lot like fractional jobs in linear relaxation methods, and fractional solutions are usually easier to find.
