Received 4 March 1995; received in revised form 6 January 1998; accepted 31 July 1998

Abstract

We present a new and general approach for defining, understanding, and computing logic programming semantics. We consider disjunctive programs for generality, but our results are still interesting if specialized to normal programs. Our framework consists of two parts: (a) a semantical, where semantics are defined in an abstract way as the weakest semantics satisfying certain properties, and (b) a procedural, namely a bottom-up query evaluation method based on operators working on conditional facts. As to (a), we concentrate in this paper on a particular set of abstract properties (the most important being the unfolding or partial evaluation property GPPE) and define a new semantics D-WFS, which extends WFS and GCWA. We also mention that various other semantics, like Fitting's comp3, Schlipf's WFSc, Gelfond and Lifschitz' STABLE and Ross and Topor's WGCWA (also introduced independently by Rajasekar et al. (A. Rajasekar, J. Lobo, J. Minker, Journal of Automated Reasoning 5 (1989) 293–307), can be captured in our framework. In (b) we compute for any program P a residual program res(P), and show that res(P) is equivalent to the original program under very general conditions on the semantics (which are satisfied, e.g., by the well-founded, stable, stationary, and static semantics). Many queries with respect to these semantics can already be answered on the basis of the residual program. In fact, res(P) is complete for D-WFS, WFS and GCWA. © 1999 Elsevier Science Inc. 1. Introduction

Already for normal programs, there are quite a lot of proposed semantics, but for disjunctive programs, the number of possibilities explodes (for an overview and comparison, see Refs. [26,27] for normal, and [28,7,32] for disjunctive programs).

In this paper, we introduce a simple, but powerful framework for analyzing, defining, and computing semantics based on elementary program transformations. For instance, we require that if \( A \) appears in no rule head, then it should be possible to evaluate occurrences of \( \lnot A \) by true, i.e. to delete \( \lnot A \) from all rule bodies. For many semantics it is also possible to delete a tautological rule like \( p \leftarrow p \) without changing the meaning of the program: this is essentially the step away from classical logic programming semantics (such as Clark’s completion [19] and its variants) to much stronger non-monotonic (or deductive database) semantics (such as WFS and STABLE). Other important transformations are unfolding (partial evaluation) and the evaluation of negative body literals in trivial cases.

Our approach has semantical as well as computational consequences. With respect to semantics, our main results are:

1. New characterizations of the standard well-founded semantics [59] as well as of the generalized closed world assumption GCWA [44] as the weakest semantics allowing our elementary transformations. “Weakest” is meant in the sense of the information ordering: any ground literal whose truth value does not become obvious by our very simple transformations is undefined in the well-founded model. This shows again how natural WFS and GCWA are.

2. When we look at disjunctive programs, the same transformations allow us to define a disjunctive extension of the well-founded semantics, which we call D-WFS. This disjunctive counterpart of WFS has good properties and a natural behaviour, and allows some important transformations already by definition.

3. While we exemplify this method for defining/characterizing semantics in depth only in the case of WFS/D-WFS, it works also with other sets of program transformations or other definitions of the universe of “abstract semantics”, which we study. For example Fitting’s 3-valued version \( \text{comp}_3 \) of Clark’s completion [37], Schlipf’s well-founded by case semantics WFS_c [53], Gelfond and Lifschitz’s STABLE [38,39] and Ross and Topor’s WGCWA [38,39] can be captured with appropriate transformation rules.

We believe that many interesting results will be possible by applying our ideas in slightly modified frameworks. It is important to look at the space of all possible abstract semantics, because otherwise it can be only by chance that we know certain semantics. There could be semantics with much better properties, which are, however, yet unknown.

4. We also show that a subset of our transformations exactly characterizes those semantics which look only at the minimal models of the given program, and not at its syntax.

Our approach also contributes to the computation of semantics. In particular we develop a bottom-up computation of semantics allowing our elementary transformations:

1. We show that a normal form, called the residual program, can be constructed by our elementary transformations from every (disjunctive) logic program. The residual program consists of conditional facts, i.e. ground rules without positive body
Conditional facts result from delaying the negative body literals during a bottom-up evaluation of an allowed logic program (the delayed literals are attached as "conditions" to the derived facts). Conditional facts have already been studied in Refs. [14, 15, 30, 29, 42] (for non-disjunctive programs). We especially generalize the $T_p$-operator and the reductions introduced by Bry to the disjunctive case. However, our main result is the relation of this bottom-up computation to our elementary program transformations.

2. A consequence of this is that the residual program is equivalent to the original program for any semantics allowing our elementary program transformations. Besides the wellfounded semantics and our D-WFS, for instance also the stable model semantics (for normal and disjunctive programs), the well-founded-by-case semantics [53] as well as the static [49] and stationary [47] semantics satisfy this condition. For every such semantics, the computation of the residual program can be a useful preprocessing step, because it is equivalent to the original program, but it is ground and contains no positive body literals (and usually very few negative body literals).

In the case of WFS and D-WFS, the truth value of all ground atoms can be trivially decided based on the residual program: if there is a fact $A \leftarrow true$, $A$ is true, and if $A$ does not occur in any rule head, $A$ is false. All other ground atoms are undefined. For other semantics, like the stable model semantics, only the few "islands of complexity" remain. They must be evaluated with other techniques.

3. It also directly follows from our results that any semantics allowing our transformations is not changed by adding atoms which are true in the well-founded model (see Section 4.5). This is an important property extensively used in the recent method of Niemelä and Simons [46] for computing stable models. Because WFS is of quadratic complexity, and therefore located one level below the stable semantics, this property tells us that first computing WFS does no harm to the set of stable models. It is a restricted form of cautious monotony which pays off from the computational viewpoint. See also Ref. [24].

4. Although originally we developed our program transformations just for declarative purposes (we wanted a semantics to satisfy some natural conditions) and used them to prove a completeness result with respect to our bottom-up procedure, it is also possible to apply them to a given program and compute the normal form directly. This works because our calculus of transformations is confluent and terminating: the normal form is therefore uniquely terminated. This use of our transformations is worked out in detail in Ref. [6], and we refer the reader to this article.

Let us finally mention related work. Transformational approaches have been considered in Refs. [31, 18]. While in Ref. [31], abstract properties have been used only for speeding up query evaluation in Ref. [18], the main focus of the program transformation is to make explicit possible uses of disjunctive information. In Ref. [20], also a "residual program" is computed, but this is done top-down, and their processing of the residual program is quite different. Partial evaluation (unfolding) has also been studied in Refs. [56, 57].

Our paper is structured as follows: in Section 2, we first introduce an abstract notion of logic programming semantics. Then we define the elementary program transformations which we use in this paper. We define our semantics D-WFS as the weakest abstract semantics allowing these transformation. At the end of Section 2, we explain that this method for defining and characterizing semantics is in fact much more general, and can be applied to other semantics as well.
In Section 3, we develop a bottom-up query evaluation algorithm based on conditional facts and the residual program. We also give an alternative characterization of the residual program which generalizes to infinite programs or programs with function symbols.

Section 4 contains our main results. We first show that the computed semantics is indeed our abstractly characterized semantics D-WFS. However, we prove in fact much more, namely that the residual program can be reached from the original program by means of our elementary transformations (it is the uniquely determined normal form). This allows to use the computation of the residual program as a preprocessing step for other semantics as well. We also prove a nice characterization of the semantics allowing a subset of our transformations in terms of minimal models. We conclude Section 4 with a proof that it is possible to evaluate literals whose truth value is known in the well-founded model also in any other semantics allowing our transformations. We claim that this is an important property for computing stable models more efficiently (as is well known, computing stable models is an NP-complete problem, therefore a really efficient, i.e. polynomial algorithm is unlikely to exist). However, substantiating this claim will be subject to future research.

In Section 5 we explain how D-WFS relates to various other semantics. In particular, we establish the equivalence to the classical well-founded semantics for non-dsjunctive programs and to the generalized closed world assumption for positive disjunctive programs. This shows that our results indeed give a nice characterization of the classical WFS.

Computational properties are shortly discussed in Section 6. Finally, we give a short summary and an outlook on future work in Section 7. Most of the proofs have been given in Appendices A–D.

2. Abstract semantics and transformations

In this paper, we consider allowed disjunctive DATALOG programs over some fixed function-free finite signature $\Sigma$. In fact, in the semantical part of this paper, we consider only the ground instantiation of the programs, because we claim that any sensible semantics should assign the same meaning to a program $P$ and its instantiation $\text{ground}(P)$. So the variables are seen only as a shorthand for denoting ground programs in a more compact way. This means that in the semantical part, we could as well have worked with propositional programs.

However, in the computational part, it would be very inefficient to compute first the ground instantiation of the given program. Here we make use of the allowedness condition: every variable of the rule must occur also in a positive body literal. This guarantees that in every rule application, all variables are bound to a constant. It is true that in this way we again manage to consider only ground programs. But we do not consider the complete instantiation of the program – only rule instances with possibly true body literals. We never consider a rule instance containing a positive body literal which does not match any previously derived "conditional fact".

Let us finally clarify the requirement that we work with a fixed finite function-free signature.

1. The signature must be fixed, because our program transformations may change the set of actually occurring symbols, but we wish to keep the syntactic base.
2. In some of our theorems we need that the instantiated program is finite. Of course, this is an important restriction, but it was very fruitful and has led to a very nice theory.

3. Furthermore, from a more practical viewpoint, we also have to avoid infinite loops. Note that for arbitrary first-order programs, even the well-founded semantics is highly undecidable ($\Pi_1^1$-complete over the integers, see Ref. [54]). Therefore, we cannot capture such a semantics with elementary and constructive transformation rules.

For the semantical part, our assumptions are not real restrictions: we have shown in Ref. [36] that our semantical framework can be generalized to arbitrary disjunctive first-order programs by introducing a non-constructive Loop-Detection Rule. This rule is also a transformation rule but in contrast to the rules we consider here, testing whether it can be applied to a particular program is not decidable (this is similar to local stratifiability).

Even our bottom-up procedure (to be introduced in the next section) is easily generalized to handle infinite propositional programs (see Section 3.3). Thus our assumptions can be seen as suitable properties to ensure feasible computations, but not as essentially built-in restrictions of our overall framework.

**Definition 2.1 (Logic program).** A logic program $P$ is a finite set of rules of the form

$$A_1 \lor \cdots \lor A_k \leftarrow B_1 \land \cdots \land B_m \land \lnot C_1 \land \cdots \land \lnot C_n,$$

where the $A_i/B_i/C_i$ are $\Sigma$-atoms, $k \geq 1$, $m \geq 0$, $n \geq 0$, and every variable of the rule appears in one of the $B_i$ (allowedness). We identify such a rule with the triple consisting of the sets of atoms

$$\mathcal{A} := \{A_1, \ldots, A_k\}, \quad \mathcal{B} := \{B_1, \ldots, B_m\}, \quad \mathcal{C} := \{C_1, \ldots, C_n\},$$

and write it as $\mathcal{A} \leftarrow \mathcal{B} \land \lnot \mathcal{C}$. The set of all logic programs over $\Sigma$ will be denoted by $LP_\Sigma$.

**Definition 2.2 (Instantiation, possibly true facts).** We write $\text{ground}(P)$ for the full instantiation of $P$ (with respect to $\Sigma$) and $\text{heads}(P)$ for the set of ground atoms occurring in rule heads in $\text{ground}(P)$.

### 2.1. Logic programming semantics

Our definition of a logic programming semantics is a very general one. We simply assume that a semantics maps every logic program into a set of pure ground disjunctions. We sometimes call these disjunctions deduced formulae, simply meaning that they follow under the semantics.

This includes for instance “model-theoretic semantics” such as the stable model semantics, which define a set of models for every logic program. We simply deduce those ground disjunctions which are true in all of these models (sceptical view). Also, if a semantics assigns to every program a completion (i.e. a first-order theory), then we take the pure disjunctions which follow from this completion. Pure disjunc-

---

3 To be precise, the rule operates on arbitrary infinite propositional programs.
tions consist either of only positive or of only negative literals; there are no atoms and negative literals at the same time (no mixed disjunctions).

Of course, the question arises why we are only interested in deducing pure ground disjunctions:

- First, non-ground (universally quantified) formulas cannot be deduced from allowed logic programs.
- Second, it is natural to assume that \( Q_1 \land Q_2 \) is implied if and only if both, \( Q_1 \) as well as \( Q_2 \), are implied. So a semantics has no freedom to decide which (ground) conjunctions are implied and which are not.
- However, for disjunctions it is possible that \( Q_1 \lor Q_2 \) is implied, but neither \( Q_1 \) nor \( Q_2 \) are implied. Therefore it does not suffice to look only at implied ground literals.
- Third, we look only at pure disjunctions because we believe that there is a difference between a logic programming system and an automatic theorem prover. We do not want to conclude implied rules, for instance, but we are interested to answer queries. For instance, the STATIC semantics allows unfolding as long as we look only at the implied pure disjunctions, but unfolding is no equivalence transformation if we look at all possible consequences. As an example, consider the following logic program:

\[
\begin{align*}
p \lor q. \\
r \leftarrow p.
\end{align*}
\]

Unfolding the body literal \( p \) yields the logic program

\[
\begin{align*}
p \lor q. \\
r \lor q.
\end{align*}
\]

While the first program obviously implies the rule \( r \leftarrow p \), this is not true for the second program under the STATIC semantics. However, the two programs are equivalent under the STATIC semantics as long as we look only at pure disjunctions (because then only the minimal models of the program are needed).
- Finally, we will define in this paper a disjunctive extension of the well-founded semantics. The standard well-founded semantics for normal programs can be seen as defining sets of positive and negative ground literals which can be concluded from the program. Therefore, it seems natural to extend this in the disjunctive case to positive and negative ground disjunctions.

But in fact, a large part of our theory does not depend on the exact definition of a semantics, and therefore it can be considered as a real framework (see Section 2.4).

**Definition 2.3** (Semantics). A semantics \( \mathcal{S} \) is a mapping which assigns to every logic program \( P \in LP_\Sigma \) a set \( \mathcal{S}(P) \) of pure disjunctions of ground literals over \( \Sigma \). It must satisfy the following requirements:

1. \( \mathcal{S}(P) = \mathcal{S}(\text{ground}(P)) \) (instantiation invariance).
2. If \( Q \in \mathcal{S}(P) \) and \( Q \subseteq Q' \) (i.e. \( Q \) is a subdisjunction of \( Q' \)), then \( Q' \in \mathcal{S}(P) \) (right weakening).
3. If \( \mathcal{A} \leftarrow \text{true} \in P \) for a disjunction \( \mathcal{A} \), then \( \mathcal{A} \in \mathcal{S}(P) \) (necessarily true).
4. If \( \mathcal{A} \notin \text{heads}(P) \) for some \( \Sigma \)-ground atom \( \mathcal{A} \), then \( \text{not} \; \mathcal{A} \in \mathcal{S}(P) \) (nec. false).

If \( Q \in \mathcal{S}(P) \), we also write \( P \models \mathcal{Q} \).
This is a very general definition, and practically all proposed semantics fit into this framework.

It might be argued at this point that our definition is in fact too general, because it does not even guarantee closure under logical consequences. For instance, consider the following program $P$:

\[
p.
\]
\[
q \leftarrow p.
\]

Every semantics must allow to conclude $p$, but $q$ is not necessarily contained in $\mathcal{S}(P)$. Of course, our semantics D-WFS is closed under logic consequences (Theorem 4), but this is something we have to prove. There is nothing bad in allowing also strange semantics in the beginning. Our characterizations get only stronger by starting with such weak requirements in the basic definition.

Note also that our notion of a semantics does not necessarily restrict us to consider only Herbrand-models (although this is one of the main applications). This is because the underlying signature can contain additional constants, not occurring in the given program. Such additional constants often have the effect to avoid problems related to Herbrand-domains, such as the universal-query-problem (see Refs. [41,28]).

2.2. Program transformations

We base our discussion on abstract properties of logic programming semantics. All of them require that certain elementary transformations do not change the semantics of a given logic program.

**Definition 2.4 (Program transformation).** A program transformation is any binary relation $\sim$ between instantiated logic programs.

For the sake of simplicity, we consider only ground logic programs in the semantical part. This is possible since we have required "instantiation invariance" in our definition of a semantics: a semantics is already completely defined by its values for ground programs.

Note that a program transformation is a relation, and not a function, because we consider only elementary changes like deleting a single tautological rule. This makes it simpler to prove that a semantics allows such a transformation. We have shown in Ref. [18] that the rewriting system consisting of the transformations which we consider here is terminating and confluent.

**Definition 2.5 (Equivalence transformation).** We call a transformation $\rightarrow$ an $\mathcal{S}$-equivalence transformation iff $\mathcal{S}(P_1) = \mathcal{S}(P_2)$ for all ground programs $P_1$ and $P_2$ with $P_1 \rightarrow P_2$. In this case, we also say that the semantics $\mathcal{S}$ allows the transformation $\rightarrow$.

An very important such transformation is partial evaluation in the sense of the "unfolding" operation. It is the "Generalized Principle of Partial Evaluation (GPPE)" [33,5] (it has also been considered by Sakama and Seki in Refs. [56,57] under the name partial deduction). For ground normal logic programs, unfolding
simply means to replace a positive body literal by all bodies of rules having this literal in the head. For instance, suppose there are only the following two rules about $q$:

$$ q \leftarrow s_1 \land \neg t. $$

$$ q \leftarrow s_2. $$

Then, if we unfold $q$ in the rule $p \leftarrow q \land \neg r$, we get the rules

$$ p \leftarrow s_1 \land \neg t \land \neg r. $$

$$ p \leftarrow s_2 \land \neg r. $$

The original rule $p \leftarrow q \land \neg r$ is replaced by these two new rules, i.e. it is not contained in the resulting program. In the case of disjunctive programs, we must also treat a possible disjunctive context of the unfolded literal in a rule head. The formal definition is as follows.

**Definition 2.6** (GPPE). A ground program $P_2$ results from a ground program $P_1$ by unfolding $(P_1 \rightarrow u P_2)$ iff there is a rule $\mathcal{A} \leftarrow (\mathcal{A} \cup \{B\}) \cup \neg \mathcal{C}$ in $P_1$ such that

$$ P_2 = P_1 - \{ \mathcal{A} \leftarrow (\mathcal{A} \cup \{B\}) \cup \neg \mathcal{C} \} $$

$$ \cup \{ \mathcal{A} \cup (\mathcal{A}' - \{B\}) \leftarrow (\mathcal{A} \cup \mathcal{A}') \land \neg (\mathcal{C} \cup \mathcal{C}') \mid \mathcal{A}' \leftarrow \mathcal{A}' \land \neg \mathcal{C}' \text{ is a rule in } P_1 \text{ with } B \in \mathcal{A}' \}. $$

We will need also a weak version of GPPE, which does not eliminate the original rule, but only adds the result of unfolding:

**Definition 2.7** (Weak GPPE). A ground program $P_2$ results from a ground program $P_1$ by weak unfolding $(P_1 \rightarrow w P_2)$ iff there is a rule $\mathcal{A} \leftarrow (\mathcal{A} \cup \{B\}) \cup \neg \mathcal{C}$ in $P_1$ such that

$$ P_2 = P_1 \cup \{ \mathcal{A} \cup (\mathcal{A}' - \{B\}) \leftarrow (\mathcal{A} \cup \mathcal{A}') \land \neg (\mathcal{C} \cup \mathcal{C}') \mid \mathcal{A}' \leftarrow \mathcal{A}' \land \neg \mathcal{C}' \text{ is a rule in } P_1 \text{ with } B \in \mathcal{A}' \}. $$

The next property we need is that tautological clauses like $p \leftarrow p$ do not influence the semantics of a logic program. Note that tautologies never imply new facts in non-disjunctive programs (we must know $p$ already in order to derive $p$ by means of such a rule). In disjunctive programs, rules like $p \lor q \leftarrow p$ can imply subsumed (non-minimal) disjunctive facts, which we will consider also as irrelevant here (see below). This and the following property together correspond to the "equivalence" principle of Ref. [27]. They require that it should be possible to delete obviously redundant rules.

**Definition 2.8** (Elimination of tautologies). A ground program $P_2$ results from a ground program $P_1$ by elimination of tautologies $(P_1 \rightarrow r P_2)$ iff there is a rule $\mathcal{A} \leftarrow \mathcal{A} \land \neg \mathcal{C}$ in $P_1$ such that $\mathcal{A} \land \mathcal{A} \neq \emptyset$ and $P_2 = P_1 - \{ \mathcal{A} \leftarrow \mathcal{A} \land \neg \mathcal{C} \}.$

**Lemma 2.1.** If a semantics $\mathcal{A}$ allows unfolding and the elimination of tautologies, it also allows weak unfolding.
Proof. Let $P_1 \hookrightarrow_w P_2$ and let $B$ be the unfolded literal.

(1) If $P_1$ contains the tautology $B \leftarrow B$, unfolding and weak unfolding give the same result, because the rule head $\leftarrow (B \land \{B\})$ does not hold in $P_1$ and hence $\mathcal{F}(P_1) = \mathcal{F}(P_2)$.

(2) If $P_1$ does not contain this tautology, let $P'_1 := P_1 \cup \{B \leftarrow B\}$ and $P'_2 := P_2 \cup \{B \leftarrow B\}$. So we have $P'_1 \hookrightarrow_r P_1$ and $P'_2 \hookrightarrow_r P_2$. As explained above, $P'_1 \hookrightarrow_r P'_2$ holds. But since $\mathcal{F}$ allows $\hookrightarrow_r$ and $\hookrightarrow_u$, we have $\mathcal{F}(P_1) = \mathcal{F}(P'_1) = \mathcal{F}(P'_2) = \mathcal{F}(P_2)$. □

The next transformation allows to delete a rule if we already have a stronger rule. For instance, $p \leftarrow q \land \neg r$ is not necessary if we also have the rule $p \leftarrow q$. This transformation is possible for all proposed semantics for normal programs. In the case of disjunctive programs, it also allows to delete a rule like $p \lor q \leftarrow r$ if there is already the rule $p \leftarrow r$. Therefore it is satisfied only for semantics with the non-inclusive interpretation of $\lor$.

**Definition 2.9 (Elimination of non-minimal rules).** A ground program $P_2$ results from a ground program $P_1$ by elimination of non-minimal rules ($P_1 \hookrightarrow_{\text{NM}} P_2$) iff there are two distinct rules $\mathcal{A} \leftarrow B \land \neg C$ and $\mathcal{A}' \leftarrow B' \land \neg C'$ in $P_1$ such that $\mathcal{A}' \subseteq \mathcal{A}$, $B' \subseteq B$, $C' \subseteq C$, and $P_2 = P_1 - \{\mathcal{A} \leftarrow B \land \neg C\}$.

We already required that $\neg A$ should be derivable if $A$ appears in no rule head. But then it should be possible to evaluate the body literal $\neg A$ to true, i.e. to delete $\neg A$ from all rule bodies: this is guaranteed by Positive Reduction. As an example, we can replace $p \leftarrow q \land \neg r$ by $p \leftarrow q$ if $r$ does not appear in any rule head.

**Definition 2.10 (Positive reduction).** A ground program $P_2$ results from a ground program $P_1$ by positive reduction ($P_1 \hookrightarrow_{\text{P}} P_2$) iff there is a rule $\mathcal{A} \leftarrow B \land \neg C$ in $P_1$ and $C \in \mathcal{C}$ such that $C \notin \text{heads}(P_1)$ and

\[
P_2 = P_1 - \{\mathcal{A} \leftarrow B \land \neg C\} \cup \{\mathcal{A}' \leftarrow B' \land \neg (C - \{C\})\}.
\]

Conversely, if the logic program contains $A_1 \lor \cdots \lor A_k \leftarrow \text{true}$, at least one of these atoms must be true, so a rule body containing $\neg A_1 \land \cdots \land \neg A_k$ is surely false, therefore the entire rule is useless, and it should be possible to delete it: this gives us Negative Reduction.

**Definition 2.11 (Negative reduction).** Let $P_1$ and $P_2$ be ground programs. $P_1 \hookrightarrow_{\text{NM}} P_2$ iff there are rules $\mathcal{A} \leftarrow B \land \neg C$ and $\mathcal{A}' \leftarrow \text{true}$ in $P_1$ such that $\mathcal{A}' \subseteq \mathcal{A}$ and $P_2 = P_1 - \{\mathcal{A} \leftarrow B \land \neg C\}$.

These notions of reduction have been introduced in Ref. [25] for normal programs and in Ref. [32] for disjunctive programs. It turned out that an application of these principles may reduce the size of a program drastically, because many literals are decided to be true or false.

Let us now introduce names for various interesting combinations of the above elementary transformations.
Definition 2.12 (Combined transformations).
- Let $\mapsto_{UAD} := \mapsto_U \cup \mapsto_W \cup \mapsto_T$, i.e. the combination of unfolding, weak unfolding, and the elimination of tautologies.
- Let $\mapsto_{MPN} := \mapsto_M \cup \mapsto_P \cup \mapsto_N$, i.e. the combination of the above "reduction" transformations.
- Let $\mapsto_{un} := \mapsto_{UAD} \cup \mapsto_{MPN}$, i.e. the combination of all the above transformations.
- Let $\mapsto_{dwh} := \mapsto_U \cup \mapsto_T \cup \mapsto_M \cup \mapsto_P \cup \mapsto_N$ be the combination of the five transformations which characterize our semantics D-WFS (all the above transformations except weak unfolding which is redundant by Lemma 2.1).
- Finally, let $\mapsto_{mod} := \mapsto_U \cup \mapsto_W \cup \mapsto_T \cup \mapsto_M$, i.e. the transformations which do not change minimal models.

Note that our properties make sense for semantics like GCWA and WFS, which are defined only on positive resp. normal programs, because these classes of programs are closed under our transformations.

2.3. Definition of a disjunctive well-founded semantics

If we now look at the space of all possible abstract semantics, there are of course many semantics allowing the above transformations. However, we will show that there is one uniquely determined weakest semantics.

Definition 2.13 (Weaker semantics). We call a semantics $\mathcal{S}_1$ weaker than a semantics $\mathcal{S}_2$ (i.e. $\mathcal{S}_1 \subseteq \mathcal{S}_2$) iff $\mathcal{S}_1(P) \subseteq \mathcal{S}_2(P)$ for all programs $P$.

Lemma 2.2. The set of semantics ordered by $\subseteq$ is a complete lattice.

Proof. Obviously, $\subseteq$ is a partial order (we denote in the following with $P$ a program and with $Q$ a pure disjunction):

$$\mathcal{S}_1 \subseteq \mathcal{S}_2 \iff \{ (P, Q) \mid Q \in \mathcal{S}_1(P) \} \subseteq \{ (P, Q) \mid Q \in \mathcal{S}_2(P) \}.$$ 

The least upper bound and greatest lower bound are also computed as in the standard powerset lattice, namely we take the union resp. intersection of the sets $\mathcal{S}(P)$. It is easy to check that the resulting mapping is indeed a semantics according to our definition. 

We introduce the following notation for the weakest possible semantics (the bottom element of the lattice):

Definition 2.14 (Known disjunctive facts). Let known be the semantics defined by:

1. For a positive ground disjunction $Q$:

$$Q \in \text{known}(P) : \iff \text{there is } \mathcal{C} \subseteq Q \text{ with } \mathcal{C} \leftarrow \text{truc} \in \text{ground}(P).$$

2. For a negative ground disjunction $Q$:

$$Q \in \text{known}(P) : \iff \text{there is not } A \in Q \text{ with } A \notin \text{heads}(P).$$
Lemma 2.3. Let \( \text{SEM} \) be a set of semantics allowing a transformation \( \rightarrow \). Then \( \text{lub}(\text{SEM}) \) and \( \text{glb}(\text{SEM}) \) also allow \( \rightarrow \).

Proof. Let \( P_1 \) and \( P_2 \) be any ground programs with \( P_1 \rightarrow P_2 \). Then we have for all \( \mathcal{S} \in \text{SEM} \): \( \mathcal{S}(P_1) = \mathcal{S}(P_2) \). For the greatest lower bound, we have:

\[
(\text{glb}(\text{SEM}))(P_1) = \bigcap_{\mathcal{S} \in \text{SEM}} (\mathcal{S}(P_1)) = \bigcap_{\mathcal{S} \in \text{SEM}} (\mathcal{S}(P_2)) = (\text{glb}(\text{SEM}))(P_2).
\]

The same works for \( \text{lub} \) (with \( \cup \) instead of \( \cap \)). \( \square \)

Theorem 2.1 (Weakest semantics). For any transformation \( \rightarrow \) there is a unique weakest semantics \( \mathcal{S}_{\text{w}} \) allowing the transformation \( \rightarrow \).

Proof. This is trivial: we simply take the greatest lower bound of all semantics allowing the transformation \( \rightarrow \). By Lemma 2.3 it also allows \( \rightarrow \). \( \square \)

However, there is also a more constructive proof. Let us denote by \( \equiv \) the reflexive, symmetric, and transitive closure of the transformation \( \rightarrow \). Then we define:

\[
\mathcal{S}_{\ldots}(P) := \bigcup_{P' \text{ ground } P} \text{known}(P').
\]

From this construction it is clear that \( \mathcal{S}_{\ldots} \) is invariant under the transformations and that any other semantics \( \mathcal{S} \) with these properties must at least derive the same disjunctions, so \( \mathcal{S}_{\ldots} \subseteq \mathcal{S} \).

Definition 2.15 (D-WFS). The semantics D-WFS is defined as the weakest semantics allowing unfolding, elimination of tautologies and non-minimal rules, and positive and negative reduction, i.e. the weakest semantics allowing the transformation \( \text{D-WFS} \).

Note that at this point it is still possible that the semantics is inconsistent, i.e. that for some \( P \) and \( A_1, \ldots, A_n \), it is possible that \( A_1 \lor \cdots \lor A_n \in \text{D-WFS}(P) \), and \( \not A_i \notin \text{D-WFS}(P) \) for \( i = 1, \ldots, n \). This is no particular failure of this way to define a semantics, because other prominent semantics such as STABLE can be inconsistent, too. It would simply mean that the required properties are too strong. However, as will become clear from the characterization in the next section, our semantics D-WFS is always consistent. In fact, it is a rather weak semantics.

We note that the restriction to a function-free and finite signature is essential in this section. Our reductions do not allow us to "unfold infinite loops". Let us consider the program consisting of the single rule

\[
p(X) \leftarrow p(f(X))
\]

(or the equivalent infinite ground program). If D-WFS were defined for such programs as above, it would not be able to derive \( \not p(t) \) from this program. So we need that the ground instantiation of all considered programs is finite.

However, as already mentioned before Definition 2.1, the non-constructive Loop-Detection Rule of Ref. [30] allows to derive \( \not p(t) \).
2.4. A framework for defining semantics

Let us conclude this section by noting that the proposed method for defining and characterizing semantics is in fact a very general one. The idea is to
1. Define a space of candidate semantics as mappings from logic programs to some “semantic domain”, satisfying certain minimal requirements. These semantics should be ordered by a “weaker” relation $\sqsubseteq$.
2. Select a number of good properties the semantics should have. It is important that these properties are inherited to the greatest lower bound of semantics satisfying them. This is automatically satisfied for properties of the form considered here (that certain program transformations do not change the semantics) if the relation $\sqsubseteq$ is derived from some order on the semantic domain by pointwise comparison for all programs.
3. Look at the $\sqsubseteq$-smallest semantics having the properties.

For instance, in Ref. [5], we have defined a semantics modeltheoretically as a mapping which assigns to every logic program $P$ a set of 3-valued Herbrand models of $P$ (subject to the condition that atoms not occurring in $P$ are interpreted as false). So the semantic domain consists of sets of 3-valued Herbrand interpretations. A semantics is stronger iff it allows less models, so we define

$$\mathcal{S}_1 \sqsubseteq \mathcal{S}_2 \iff \text{for all } P: \mathcal{S}_1(P) \supseteq \mathcal{S}_2(P).$$

In order to show that not only D-WFS can be captured in our framework, we need to introduce two further transformation rules.

Definition 2.16 (Elimination of contradictions, supraclascicality). A ground program $P_2$ results from a ground program $P_1$ by elimination of contradictions ($P_1 \leftarrow \uparrow P_2$) iff there is a rule $\mathcal{A} \leftarrow \mathcal{B} \wedge \text{not } \mathcal{C}$ in $P_1$ such that $\mathcal{B} \cap \mathcal{C} \neq \emptyset$ and $P_2 = P_1 - \{ \mathcal{A} \leftarrow \mathcal{B} \wedge \text{not } \mathcal{C} \}$.

A ground program $P_2$ results from a ground program $P_1$ by applying supraclascicality ($P_1 \leftarrow \uparrow P_2$) iff there is an atom $A$ such that $P_1 \models A$ and $P_2 = P_1 \cup \{ A \leftarrow \}$. (Here $P_1 \models A$ just means classical entailment: $P_1$ is viewed as a propositional theory and $A$ as an atom therein.

Elimination of contradictions just means to eliminate rules with contradicting bodies, like $p \vee q \leftarrow r, s, \text{not } r, \text{not } q$. Supraclassicality means that whenever an atom $A$ follows classically from the program (viewed as a classical theory), then this atom can be safely added to the program. This formalizes the property that the semantics should be at least as strong as classical logic.

We are now able to state the following theorems, the proofs of which can be found in Ref. [5], Theorem 4.1; [5], Theorem 4.4 and [26], Theorem 4.9.

Theorem 2.2 (GCWA, STABLE and WFS as weakest semantics).
1. GCWA is the weakest semantics for positive disjunctive programs satisfying positive and negative reduction, GPPE and elimination of tautologies.
2. STABLE is the weakest semantics for arbitrary disjunctive programs satisfying positive and negative reduction, GPPE, elimination of tautologies and elimination of contradictions.
3. \( WFS_C \) is the weakest semantics for non-disjunctive programs satisfying positive and negative reduction, GPPE, elimination of tautologies and supra-classicality.

In all the above semantics, elimination of tautologies was an important ingredient. But we can also capture semantics where this transformation does not hold. In fact, we need only two very special cases of the GPPE rule: Success and Failure.

**Definition 2.17 (Success and failure).** The success-transformation can be applied to a program \( P \) whenever there is a rule \( A \leftarrow \) in \( P \). Success then removes a positive occurrence of \( A \) in the body of another rule.

Dually, the failure-transformation can be applied to a program \( P \) whenever there is a an atom \( A \) which does not occur in any head of a rule. Failure then removes a rule which contains \( A \) positively in its body.

The following theorem is contained in Ref. [24], Theorem 5.3.

**Theorem 2.3** (comp\(_3\) (resp. lfp(\(\Phi_P\)) as weakest semantics). Fitting's semantics comp\(_3\) (which is defined as lfp(\(\Phi_P\))) is the weakest semantics for non-disjunctive programs satisfying success, failure, positive and negative reduction.

The following table (from Ref. [4]) gives an overview which semantics allow which transformations. The entry "\(\bullet\)" means that the corresponding property holds, "\(-\)" means that it does not hold. We have not included an entry for positive or negative Reduction, because these conditions hold for all semantics listed below.

### Properties of logic programming semantics

We strongly conjecture that other interesting results can be achieved by modifying the basic requirements on the semantics and possibly by looking at other properties. Many of the results and techniques of this paper will remain applicable, because they only refer to program transformations.

\(\dagger\) WGCWA is equivalent to the semantics introduced by Ross and Topor in Ref. [52].
3. Bottom-up query evaluation

In this section we explain how to compute a normal form of the given program, called the residual program. In contrast to the last section, we no longer work on instantiated programs. However, we use the allowedness-condition to bind the variables and avoid floundering. Our approach is based on the notion of conditional facts, as developed by Bry in Refs. [14,15] and Dung and Kanchansut in Refs. [30,29] (both for the non-disjunctive case). The idea is to delay the evaluation of negative body literals, and to attach them as conditions to the derived (disjunctive) facts.

Definition 3.1 (Conditional fact). A conditional fact is a rule without positive body literals, i.e. it is of the form $A_1 \lor \cdots \lor A_k \leftarrow \text{not } C_1 \land \cdots \land \text{not } C_m$, where the $A_i$ and the $C_j$ are ground atoms ($k \geq 1$, $m \geq 0$).

The necessity that the $A_i$ and $C_j$ are ground automatically follows from the allowedness restriction.

3.1. Computation of derived conditional facts

The usual bottom-up fixpoint computation is also possible with conditional facts: in the non-disjunctive case, one can simply store the conditions of a fact in an additional set-valued argument. Derived facts get the union of the conditions of the facts matched with the body literals (plus the corresponding instances of the negative body literals of the rule itself). This is demonstrated in the following example.

\[
p(a) \leftarrow \text{not } s(b) \land \text{not } r(b).
\]

\[
p(X) \leftarrow q_1(X) \land q_2(X,Y) \land \text{not } r(Y).
\]

\[
q_1(a) \quad q_2(a,b) \leftarrow \text{not } s(b)
\]

In the disjunctive case, one applies the "hyperresolution" operator by adding to every fact also a disjunctive context [17,45,12]. An implementation with database techniques has been suggested in Ref. [10]. Formally, the immediate consequence operator is generalized to conditional facts as follows:

Definition 3.2 (Immediate consequences with conditions). For a set $\Gamma$ of conditional facts we define:

\[
T_P(\Gamma) := \left\{ \left( \mathcal{A}_0 \cup \bigcup_{i=1}^m (\mathcal{A}_i - \{B_i\}) \right) \leftarrow \text{not } \left( \mathcal{A}_0 \cup \bigcup_{i=1}^m \mathcal{F}_i \right) \right\}
\]

where there are ground instances $\mathcal{A}_0 \rightarrow B_1 \land \cdots \land B_m \land \text{not } \mathcal{F}_0$ of a rule in $P$ and conditional facts $\mathcal{A}_i \rightarrow \text{not } \mathcal{F}_i \in \Gamma$ with $B_i \in \mathcal{A}_i$ ($i = 1, \ldots, m$).

Example 3.1. The following example illustrates the idea. From

\[
\text{winning}(X) \leftarrow \text{more}(X,Y) \land \text{not } \text{winning}(Y)
\]
and the fact \( \text{move}(a, b) \), we derive the conditional fact

\[
\text{winning}(a) \leftarrow \neg \text{winning}(b).
\]

If we apply the rule

\[
\text{goodstate}(X) \leftarrow \text{winning}(X) \land \neg \text{excluded}(X)
\]
to the above conditional fact, we get the rule

\[
\text{goodstate}(a) \leftarrow \neg \text{excluded}(a) \land \neg \text{winning}(b).
\]

Lemma 3.1. The operator \( T_P \) is monotonic and even continuous in the lattice of sets of conditional facts ordered by \( \subseteq \).

Proof. The proof is the same as in the standard case. \( \square \)

So we can compute the smallest fixpoint of \( T_P \) as usual: we start with \( \Gamma_0 := \emptyset \) and then iterate \( \Gamma_i := T_P(\Gamma_{i-1}) \) until nothing changes. This must happen because there are only finitely many predicates and constants to build ground atoms occurring in conditional facts, and there are only finitely many subsets of all these atoms (corresponding to head and body).

The operator \( T_P \) and the idea of using conditional facts already appeared in work of Dung and Kanchansut [29] and Bry [14, 15] for non-disjunctive programs. In Ref. [42] a somewhat related approach (again for normal programs) was defined: a semantics was reduced to programs containing only negative literals in their rule-bodies.

3.2. Application of reductions

So now we have a logic program with rules of a very particular kind, namely containing no positive body literals. The next step of the proposed query evaluation algorithm is to simplify it by means of positive and negative Reduction, and the elimination of non-minimal rules. This leads to the following reduction operator on sets of conditional facts (a generalization of reductions studied in Ref. [15]):

Definition 3.3 (Reductions of conditional facts). For a set \( \Gamma \) of conditional facts we define:

\[
R(\Gamma) := \{ \sigma / \leftarrow \neg \% \cap \text{heads}(\Gamma) \mid \sigma / \leftarrow \neg \% \in \Gamma, \quad \text{and} \\
(1) \text{there is no } \sigma' / \leftarrow \text{true} \in \Gamma \text{ with } \sigma' \subseteq \sigma, \\
(2) \text{there is no } \sigma' / \leftarrow \neg \%' \in \Gamma \text{ with } \sigma' \subseteq \sigma \text{ where at least one } \subseteq \text{ is proper} \}.
\]

We again iterate this operator until nothing changes. Since the total number of atoms occurring in \( \Gamma \) is reduced in each step, this process must come to an end.

For instance, consider the program

\[
p \leftarrow \neg q. \\
q \leftarrow \neg r.
\]
Then the first application of R evaluates r to false, so we get

\[ p \leftarrow \neg q. \]

\[ q. \]

But now R is applicable again, and deletes the first rule (because q is obviously true), so we end up with

\[ q. \]

**Definition 3.4** (Residual program). Let \( P \) be a logic program, \( \Gamma_0 := \text{lfp}(T_P) \), \( \Gamma_i := R(\Gamma_{i-1}) \), and \( n \in \mathbb{N} \) with \( \Gamma_n = \Gamma_{n-1} \). Then we call \( \text{res}(P) := \Gamma_n \) the residual program of \( P \).

Although our operators \( T_P, R \) resemble to Fitting's operator \( \Phi_P \) for non-dsjunctive programs they are used differently. Not only do they operate on conditional facts, they are also applied in such a way that for programs like \( p \leftarrow p \) we get the empty program. Therefore \( \neg p \) is derivable whereas Fitting's operator would leave \( p \) undefined.

The notion of residual program now gives us a straightforward way to define a semantics from an implementation point of view (we just described a constructive bottom-up evaluation procedure).

**Definition 3.5** (Computed semantics). We define a mapping \( \mathcal{S}_{res} \) from logic programs to sets of pure ground disjunctions by

\[ \mathcal{S}_{res}(P) := \text{known}(\text{res}(P)). \]

Of course, the so defined semantics will turn out to be our semantics \( D-WFS \). This is subject of Section 4. But first let us verify that the mapping \( \mathcal{S}_{res} \) is indeed a semantics.

**Lemma 3.2.** The mapping \( \mathcal{S}_{res} \) satisfies the conditions of a semantics.

**Lemma 3.3.** For all sets \( \Gamma \) and \( \Gamma' \) of conditional facts:

\[ \Gamma \xrightarrow{\text{MPN}} \Gamma' \implies \text{res}(\Gamma) = \text{res}(\Gamma'). \]

i.e. the result of the reduction phase is invariant under elimination of non-minimal rules as well as positive and negative Reduction.

By the way, since \( \Gamma \xrightarrow{\text{MPN}} \text{res}(\Gamma) \), this also implies the confluence of \( \xrightarrow{\text{MPN}} \) among sets of conditional facts. For implementations it is very important to know that the reductions can in fact be performed in any sequence. We have discussed data structures for this in Ref. [3].

**3.3. Alternative characterization of reduction phase**

It has been criticized that the reduction phase is not done by a standard fixpoint construction, and therefore does not generalize to the infinite case. In contrast, our \( T_P \) operator has all the nice properties of the standard operator, so \( \text{lfp}(T_P) \) is also defined for programs with an infinite ground instantiation. We solve this problem by giving an alternative construction for \( \mathcal{S}_{res} \) and the residual program. It is based
on the insight that for the reductions of our operator $R$ we need only the positive disjunctions we know already for sure, and the atoms which are no longer possibly true.

**Definition 3.6 (Reduce).** Let $\Gamma$ be a set of conditional facts. Given a set $\Delta$ of pure ground disjunctions, we write $\Delta^+$ for the positive disjunctions in $\Delta$, and $\Delta^-$ for the negative ground literals contained (as one-element disjunctions) in $\Delta$. The reduct of $\Gamma$ with respect to $\Delta$ is defined as:

$$\Gamma/\Delta := \{ \mathcal{A} \leftarrow \text{not } \{} \mathcal{C} \in \Gamma \text{ and } \}
\begin{align*}
(1) & \text{ there is no } \mathcal{A}' \in \Delta^+ \text{ with } \mathcal{A}' \subseteq \mathcal{C} \\
(2) & \text{ there is no } \mathcal{A}' \leftarrow \text{not } \mathcal{C}' \text{ in } \Gamma \text{ with } \\
& \mathcal{A}' \subseteq \mathcal{A} \text{ and } (\mathcal{C}' \subseteq \Delta^-) \subseteq (\mathcal{C} \subseteq \Delta^-) \text{ (where at least one } \subseteq \text{ is proper)}.
\end{align*}$$

**Definition 3.7 (Derivation of pure disjunctions).** For every set $\Gamma$ of conditional facts, we define an operator $D_{\Gamma}$ which derives pure ground disjunctions from pure ground disjunctions:

$$D_{\Gamma}(\Delta) := \text{known}(\Gamma/\Delta).$$

**Lemma 3.4.** The operator $D_{\Gamma}$ is monotonic (in the standard powerset lattice).

The following theorem shows that this construction is equivalent to the above definition of the residual program and $S_{res}$.

**Theorem 3.1.** Let $P$ be any (finite) logic program, and $\Gamma := \text{lfp}(T_P)$. Then:

$$S_{res}(P) = \text{lfp}(D_{\Gamma}) \text{ and } \text{res}(P) = \Gamma/\text{lfp}(S_{\Gamma}).$$

4. Main results

In Section 2, we introduced a framework to define semantics in an abstract way as mappings from programs into semantic domains. In particular we studied elementary program transformations in this setting. In Section 3 we described a constructive bottom-up procedure to compute a normal form of a program. We show in this section that both approaches are closely related. This proves that the computed semantics $S_{res}$ is identical to our semantics D-WFS, so we have soundness and completeness of our algorithm.

However, our results go much further, because they apply to any semantics allowing certain transformations. We also show a nice relation of a subset of our transformations to minimal models and consider the possibility of “lifting” definitions of semantics from residual programs to all programs.

4.1. Soundness of residual program computation

If we only know that a semantics $S$ allows unfolding (GPPE) and elimination of tautologies, we already can apply the first part of our algorithm.
Theorem 4.1 (Conditional facts can be constructed by transformations). The set of derived conditional facts can be constructed from the ground instantiation of a program by applying only unfolding, weak unfolding, and the elimination of tautologies, i.e. \( \text{ground}(P) \rightarrow^* \text{wfp}(T_P) \) holds for all programs \( P \).

Since by Lemma 2.1 a semantics which allows unfolding and the elimination of tautologies automatically also allows weak unfolding, we get the following corollary.

Corollary 4.1 (Equivalence of implied conditional facts). If a semantics \( \mathcal{S} \) allows unfolding (GPPE) and the elimination of tautologies, then \( \mathcal{S}(P) = \mathcal{S}(\text{lfp}(T_P)) \) holds for all programs \( P \).

In other words, if a semantics allows unfolding and the elimination of tautologies, then it also allows the transformation \( \text{ground}(P) \rightarrow \text{lfp}(T_P) \).

So under these weak conditions on the semantics, we can already apply the computation of the implied conditional facts as a preprocessing step. Afterwards, we still need some algorithm to compute the semantics, but instead of arbitrary programs, it has to handle only ground programs without positive body literals.

Of course, if the semantics \( \mathcal{S} \) allows in addition the elimination of non-minimal rules and positive and negative reduction, then also the application of the reduction operator \( R \) does not change the semantics of the program. So we get the following.

Corollary 4.2 (Transformations yield residual program). \( \text{ground}(P) \rightarrow_{\text{alt}} \text{res}(P) \) holds for all programs \( P \), i.e. the residual program \( \text{res}(P) \) can be reached from the ground instantiation of \( P \) by applying the elementary transformations introduced in Section 2.2.

Corollary 4.3 (Equivalence of residual program). If a semantics \( \mathcal{S} \) allows unfolding (GPPE), elimination of tautologies and of non-minimal rules, as well as positive and negative reduction, then for all programs \( P \):

\[ \mathcal{S}(P) = \mathcal{S}(\text{res}(P)). \]

Since our semantics D-WFS allows the above five transformations, we have

\[ \text{D-WFS}(P) = \text{D-WFS}(\text{res}(P)). \]

Then we get \( \text{D-WFS}(\text{res}(P)) \supseteq \text{known}(\text{res}(P)) \) by definition of semantics. Together, this implies \( \text{D-WFS}(P) \supseteq \mathcal{S}_\text{res}(P) \), i.e. the soundness of our algorithm. We will show the other direction \( "\subseteq" \) with Theorem 4.3.

However, the above result is not only useful for showing the soundness of our computation of D-WFS. For instance, consider the stable model semantics, which also allows the above five transformations. With the same argument, we get that the original program \( P \) and the residual program \( \text{res}(P) \) have the same stable models. To be precise, taking stable models is not quite a semantics in the above sense. However, we can still use Theorem 4.1 and Corollary 4.2. So the above results are independent of the exact definition of a semantics, it can be any mapping from logic programs into some semantic domain.
Of course, we still have to compute the stable models of the residual program. But in the residual program, most ground literals are already decided to be true or false – any element of known(res(P)) is also a valid consequence of the stable semantics. Only the few hard cases, the “islands of complexity” remain. For instance, if P is a non-disjunctive stratified program, then the residual program is simply a set of facts, so known(res(P)) is already the unique stable model (the perfect model in this case). So many queries can already be answered on the basis of the residual program. But even if we want the complete stable models, there are algorithms (like Ref. [11]) which are good for treating the most general case, but seem to be inefficient for simpler cases. Such algorithms can profit from our computation of the residual program as a preprocessing phase. In Ref. [3], we also proposed an algorithm for doing the remaining work in the computation of stable models (based on a disjunctive extension of Clark’s completion).

Another application is in our prototype implementation of the STATIC semantics [9]: it also consists of the computation of the residual program plus an algorithm for treating the few remaining hard cases. Again, the general algorithm would be too inefficient if applied directly to the original program, but it is good enough for evaluating the few negative body literals remaining in the residual program. Also, the general algorithm is simplified, because it does not have to treat positive body literals or variables.

4.2. Relation to minimal models

For modeltheoretically defined semantics like STABLE or STATIC, it is useful to consider the relation of our transformations to minimal models. The following interesting characterization also stresses again the importance of our transformations. We will show that a semantics allows unfolding (GPPE), the elimination of tautologies, and the elimination of non-minimal rules if and only if it looks exactly at the minimal models of the programs, and not at the syntax of the programs, i.e. we require that \( \mathcal{J}(P_1) = \mathcal{J}(P_2) \) for all programs \( P_1 \) and \( P_2 \) having the same minimal models. To be precise, let us first define what we mean by a minimal model.

**Definition 4.1 (Model).** A model of a logic program \( P \) is any set \( I \) of ground literals such that for every ground instance

\[
A_1 \lor \cdots \lor A_k \leftarrow B_1 \land \cdots \land B_m \land \text{not } C_1 \land \cdots \land \text{not } C_n.
\]

of a rule in \( P \):

\[
\{B_1, \ldots, B_m, \text{not } C_1, \ldots, \text{not } C_n\} \subseteq I \quad \rightarrow \quad \{A_1, \ldots, A_k\} \cap I \neq \emptyset.
\]

So models treat \( A \) and \( \text{not } A \) as two distinct and unrelated atoms. It is possible that they are both true or both false. Models correspond to classical models if we introduce for every predicate \( p \) a new predicate \( \text{not}_p \) and replace everywhere \( \text{not } p(\ldots) \) by \( \text{it not}_p(\ldots) \). This trick was already used in Ref. [47] and we refer to Ref. [8] for a more detailed investigation.

**Definition 4.2 (Minimal model).** A model \( I \) of a program \( P \) is minimal if there is no model \( I' \) of \( P \) such that \( I \) and \( I' \) contain the same set of negative literals, but the positive literals contained in \( I' \) are a strict subset of those in \( I \).
This definition of minimal model is inspired by the construction of static expansions [49], where the "objective literals" are minimized while the interpretation of the "belief literals" (used for negations) is kept fixed. It is a very useful notion. For instance, a stable model can be defined as a minimal model which is total and consistent, i.e. contains either \( A \) or \( \neg A \) for every ground atom \( A \) (see Ref. [5] Theorem 4.3).

With the above notion of a model, we get the following useful semantical description of the set of derived conditional facts.

**Lemma 4.1.** For every program \( P \), the operator \( T_P \) is correct and complete:

1. Every conditional fact contained in \( \text{Ifp}(T_P) \) is a logical consequence of \( P \).
2. \( \text{Ifp}(T_P) \) contains all conditional facts \( A \leftarrow \neg C \), which are logical consequences of \( P \) and which are minimal (where "minimal" means that there is no \( A' \leftarrow \neg C' \), which is also a logical consequence and satisfies \( A' \subseteq A \) and \( C' \subseteq C \), where at least one "\( \subseteq \)" is proper).

Now the transformations unfolding (GPPE), elimination of tautologies and elimination of non-minimal rules do not change the set of minimal models. This is trivial for the elimination of tautologies and non-minimal rules, because they are logical equivalence transformations, i.e. they do not change the set of models.

**Lemma 4.2.** Let \( P_1 \leftarrow \cup P_2 \). Then \( P_1 \) and \( P_2 \) have the same minimal models.

This gives us the direction: if \( \mathcal{S}(P_1) = \mathcal{S}(P_2) \) for all programs \( P_1 \) and \( P_2 \) having the same minimal models, then \( \mathcal{S} \) allows these three transformations.

The other direction is proven by showing that for every pair of distinct ground programs \( P_1 \) and \( P_2 \), which are irreducible with respect to these transformations, there is an interpretation \( I \) which is a minimal model of one of the two programs, but not of the other.

**Theorem 4.2.** (Semantics looking only at minimal models). A semantics \( \mathcal{S} \) allows unfolding (GPPE), elimination of tautologies, and elimination of non-minimal rules if and only if it satisfies the following condition:

\[
\mathcal{S}(P_1) = \mathcal{S}(P_2) \quad \text{for all programs } P_1 \text{ and } P_2 \text{ which have the same set of minimal models.}
\]

In addition, also the confluence of the rewriting system consisting of unfolding weak unfolding, elimination of tautologies and elimination of non-minimal rules follows immediately from the following facts:

1. These transformations do not change the set of minimal models.
2. The rewriting system is terminating: from every ground program \( P \), we get an irreducible program \( P' \) by first computing the set of implied conditional facts (see Theorem 4.1) and then applying the elimination of non-minimal rules as long as possible.
3. Different irreducible programs have different sets of minimal models.

So from every ground program \( P \), it is always possible to reach an irreducible program by applying these transformations, but it is not possible to get to two different
irreducible programs. Questions of confluence and termination have been further investigated in Ref. [18].

4.3. Semantics defined on the residual program

Now let us return to the computation of D-WFS, which is much simpler than STABLE or STATIC, because it can be directly answered from the residual program. The completeness of our algorithm is still missing, i.e. D-WFS(P) ⊆ $\mathcal{S}_{res}(P)$. In order to prove it, we need the following theorem which is interesting in itself.

**Theorem 4.3** (Invariance of residual program). For all ground programs $P_1, P_2$:

$$P_1 \rightarrow_{\text{alt}} P_2 \Rightarrow \text{res}(P_1) = \text{res}(P_2).$$

i.e. the residual program is invariant under the elementary program transformations considered in this paper.

This has the following astonishing corollary.

**Corollary 4.4.** (Guaranteed properties). Let $\mathcal{S}$ satisfy $\mathcal{S}(P) = \mathcal{S}(\text{res}(P))$ for all $P$. Then $\mathcal{S}$ allows unfolding (GPPE), the elimination of tautologies and of non-minimal rules, as well as positive and negative Reduction.

**Proof.** Let $P_1 \rightarrow_{\text{alt}} P_2$. Then $\mathcal{S}(P_1) = \mathcal{S}(\text{res}(P_1)) = \mathcal{S}(\text{res}(P_2)) = \mathcal{S}(P_2)$. □

This means that when we define a semantics only for residual programs, and extend it to arbitrary programs via $\mathcal{S}(P) := \mathcal{S}(\text{res}(P))$, then $\mathcal{S}$ will automatically satisfy all our properties. Of course, we have to ensure that the so defined mapping $\mathcal{S}$ is really a semantics. For our notion of semantics, this is simple. But for a model-theoretic notion of a semantics, it is important to note that not all models of $\text{res}(P)$ are also models of $P$. Supported models of $\text{res}(P)$, however, are also models of $P$. The same holds for the normal models defined below (see Lemma 4.3). We do not know yet a necessary and sufficient condition for the models of $\text{res}(P)$ to be also models of $P$ (resp. every program with the given residual program).

**Example 4.1.** Consider the following $P$:

$$p \leftarrow q.
q \lor r.$$  

Here, $\text{res}(P) = \{p \lor r, q \lor r\}$. Now $I := \{q, r\}$ is a Herbrand-model of $\text{res}(P)$ with $I \not\models P$.

From Corollary 4.4 it follows immediately that our semantics $\mathcal{S}_{res}$ has the required properties. Since D-WFS is the weakest semantics with these properties, we get $\text{D-WFS}(P) \subseteq \mathcal{S}_{res}(P)$. This is the missing completeness, so together we have $\text{D-WFS}(P) = \mathcal{S}_{res}(P)$, in other words.
Corollary 4.5 (Computation of D-WFS).

\[ Q \in \text{D-WFS}(P) \iff \text{there is } \mathcal{A} \subseteq Q \text{ with } \mathcal{A} \vdash \text{true} \in \text{res}(P) \text{ or there is not } A \in Q \text{ and } A \notin \text{heads (res}(P)) \].

Note that Corollary 4.4 is the exact converse of Corollary 4.3. They can be formulated together as follows.

\( \mathcal{A} \) allows unfolding (GPPE), positive and negative Reduction, Elimination of Tautologies and of Non-minimal Rules

if and only if

\[ \text{ground}(P) \rightarrow \text{res}(P) \text{ is an } \mathcal{A}-\text{equivalence transformation (for all } P). \]

Finally note that Theorem 4.3 together with Corollary 4.2 immediately gives us the confluence of \( \rightarrow_{\text{all}} \) [6].

4.4. Closure under logical consequences

We still have to prove that D-WFS is closed under logical consequences. In order to do this, it will be useful to have some restrictions on models of the residual program which ensure that they will be also models of the original program. We already mentioned that this holds for supported models. However, residual programs such as \( p \leftarrow \neg p \) do not have supported models. The following kind of model always exists.

Definition 4.3 (Normal model). An interpretation \( I \) is a normal model of a program \( P \) iff

1. \( I \) is a minimal model of \( P \),
2. \( I \models \neg A \) for every atom \( A \) with \( A \notin \text{heads}(P) \),
3. \( I \not\models \neg A_1 \land \cdots \land \neg A_n \) for every disjunctive fact \( A_1 \lor \cdots \lor A_n \rightarrow \text{true} \) contained in \( P \).

Lemma 4.3. If \( I \) is a normal model of \( \text{res}(P) \), it is also a normal model of \( P \).

Theorem 4.4 (Closure under logical consequences). For every program \( P \) and pure ground disjunction \( Q \):

\[ P \cup \text{D-WFS}(P) \models Q \implies Q \in \text{D-WFS}(P). \]

Of course, implication \( \vdash \) is meant here with respect to the above notion of a model (which treats \( A \) and \( \neg A \) as unrelated). However, the interpretations constructed in the proof are at least consistent.

4.5. Cumulativity for \( \text{res}(P) \)

In this section we are showing a very interesting property of our residual program, which has nice computational implications for computing stable models. Namely if a disjunction \( A_1 \lor \cdots \lor A_n \) follows from \( \text{D-WFS}(P) \), then the stable models of \( P \) and of \( P \cup \{A_1 \lor \cdots \lor A_n\} \) are identical.

This makes it possible to use D-WFS as a first step in the computation of stable models, namely by adding to \( P \) the disjunctions true in \( \text{D-WFS}(P) \). The former prop-
The property has been first noticed for the non-disjunctive case by Schlipf (see Ref. [27], Theorem 3.7). In particular, for the non-disjunctive case this means that it always pays off to first compute the well-founded semantics (which can be done in polynomial time, as opposed to computing stable models, which is one level higher in the polynomial hierarchy) and to use the results to simplify the program. In fact, this is one of the main techniques employed in Ref. [46] which is currently the fastest method to compute stable models (see also Ref. [24]).

Lemma 4.4 (Adding conditional facts).
1. \( \mathcal{A} \leftarrow \neg \mathcal{A} \in \text{lfp}(T_P) \) implies \( \text{lfp}(T_P) = \text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}}) \).
2. If in addition \( \mathcal{A} \cap \text{heads}(\text{res}(P)) = \emptyset \), then \( R(\text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}})) = R(\text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}})) \).

The proof is obvious from the definition of lfp\((T_P)\).

Corollary 4.6 (Invariance of \text{res}(P) for D-WFS-Cumulativity). Let \( \mathcal{A} \) be contained in the semantics of D-WFS\((P)\). Then
\[
\text{res}(P) = \text{res}(P \cup \{\mathcal{A}\})
\]

Proof. If \( \mathcal{A} \in \text{D-WFS}(P) \) then there is a \( \mathcal{A} \) such that:
1. \( \mathcal{A} \leftarrow \neg \mathcal{A} \in \text{lfp}(T_P) \).
2. \( \mathcal{A} \cap \mathcal{A} = \emptyset \).
3. \( \mathcal{A} \cap \text{heads}(\text{res}(P)) = \emptyset \).

Using the lemma above, we have
\[
\text{lfp}(T_P) = \text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}}).
\]

Therefore
\[
\text{res}(P) = \text{res}(P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}) = R^\omega(\text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}})).
\]

But since
\[
R(\text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}})) = R(\text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}}))
\]
we have
\[
R^\omega(\text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}})) = R^\omega(\text{lfp}(T_{P \cup \{\mathcal{A} \leftarrow \neg \mathcal{A}\}})) = \text{res}(P \cup \mathcal{A}). \quad \Box
\]

Since the residual program is a sound transformation for the disjunctive stable models semantics, we get a generalization of a theorem of Schlipf which was formulated for non-disjunctive programs ([27], Theorem 3.7).

Theorem 4.5 (Restricted cumulativity for STABLE). Let \( \mathcal{A} \) be contained in the semantics of D-WFS\((P)\). Then the programs \( P \) and \( P \cup \{\mathcal{A}\} \) have identical stable models.

Note that strengthening the assumption “\( \mathcal{A} \) contained in D-WFS\((P)\)” to “\( \mathcal{A} \) contained in STABLE\((P)\)”
is not possible: this would be exactly the cumulativity condition which does not hold for STABLE [26].

5. Comparison with other approaches

In this section, we compare our semantics D-WFS to the standard well-founded semantics for non-disjunctive programs (Section 5.1), to the disjunctive stable model semantics (Section 5.2), to the static semantics (Section 5.3), and to the GCWA (defined for positive disjunctive programs) (Section 5.4). Note that the D-WFS semantics is defined (via grounding) for arbitrary programs. The restriction to allowed Datalog programs applies only to the procedural part. It turns out that

1. D-WFS agrees with WFS and GCWA on the restricted classes of programs for which these semantics are defined.
2. D-WFS is strictly weaker than both the disjunctive stable semantics and the static semantics.

This means that D-WFS at least does not allow to derive any insensible conclusions.

From the fact that D-WFS generalizes the well-founded semantics, we can also conclude a nice characterization of the standard well-founded semantics. We believe that this characterization is an important contribution of this paper. Furthermore, it gives us a very simple algorithm to compute the well-founded model via the residual program. The computational implications are considered further in Section 6.

5.1. Relation to well-founded semantics

First, it is important to note again that the well-founded semantics really allows all of our transformations.

Theorem 5.1 (WFS allows our transformations). For non-disjunctive ground programs \( P_1 \) and \( P_2 \), if \( P_1 \Vdash_{\text{all}} P_2 \), then \( P_1 \) and \( P_2 \) have the same well-founded model.

Some of these properties have already been proven in the literature, in particular unfolding has been considered in several papers; see Ref. [1]. However, we get the possibility of unfolding here immediately from Theorem 2, so it is worth mentioning.

Once we know that the WFS has our properties, Corollary 4.3 tells us that the well-founded model of the residual program is equal to the well-founded model of the original program. This result is already known [1], but again, we get it immediately in our framework. For residual programs, due to their very simple structure, it is easy to prove that our D-WFS agrees with the standard well-founded semantics. So our semantics D-WFS is indeed a generalization of the well-founded semantics to disjunctive programs.

Theorem 5.2 (D-WFS extends WFS). Let \( P \) be a non-disjunctive program and \( Q \) be a (positive or negative) ground literal. Then we have:

\[
Q \in \text{D-WFS}(P) \iff Q \in \text{WFS}(P).
\]

But this gives us a nice characterization of the standard well-founded semantics.
Corollary 5.1 (Characterization of WFS). \( WFS \) is the weakest semantics (for non-disjunctive programs) satisfying GFPE, elimination of tautologies, elimination of non-minimal rules and positive and negative reduction.

In fact, the elimination of non-minimal rules is not even necessary. Of course, the well-founded semantics allows this transformation, but we can compute the well-founded model without it (see Section 5.5 below). At this point we can already note the following simple algorithm to compute the well-founded model via the residual program.

Corollary 5.2 (Computation of WFS). Let \( P \) be a non-disjunctive program.

1. For every positive ground literal \( A \):
   \[ A \in WFS(P) \iff (A \leftarrow true) \in res(P). \]

2. For every negative ground literal not \( A \):
   \[ \text{not } A \in WFS(P) \iff A \in \text{heads}(res(P)). \]

5.2. Relation to disjunctive stable semantics

The stable model semantics is also invariant under our transformations.

Theorem 5.3 (STABLE allows our transformations). For all ground programs \( P_1 \) and \( P_2 \), if \( P_1 \leftarrow_{all} P_2 \), then \( P_1 \) and \( P_2 \) have the same set of stable models.

The stable semantics is in fact a model-theoretic semantics, which selects some models of the given program, and not directly determines a set of implied pure ground disjunctions. But it can be turned into a semantics as defined in Section 2.

\[ Q \in \text{STABLE}(P) : \iff I \models Q \text{ for all stable models } I \text{ of } Q. \]

Since we know that the stable semantics allows our transformations and we have defined D-WFS as the weakest semantics allowing these transformations, it immediately follows that D-WFS is weaker than (or equal to) STABLE. We can also say that D-WFS is an approximation of STABLE: all consequences of D-WFS are also consequences of STABLE, but STABLE might allow to conclude more (and this is indeed the case, see below).

Corollary 5.3 (D-WFS is weaker than STABLE). Let \( P \) be any (disjunctive) logic program. If \( Q \in D-WFS(P) \), then \( Q \) holds in all stable models of \( P \). (And if \( P \) is stratified, these are exactly the perfect models.)

The following example shows that D-WFS is indeed strictly weaker than STABLE, even for stratified disjunctive programs.

Example 5.1 (D-WFS is weaker than PERFECT). Consider the following stratified disjunctive logic program due to Ross:

\[
\begin{align*}
p & \lor q. \\
r & \leftarrow \text{not } p. \\
r & \leftarrow \text{not } q.
\end{align*}
\]
Here his S-WFS as well as our semantics D-WFS leave r undefined, because p and q are undefined. In contrast, the perfect model semantics allows to conclude r, which is required for any semantics having a really exclusive or.

However, it depends on the application whether one really wants to conclude not r or not. In a similar example due to Przymusinski, p means “go to Australia”, q means “go to Europe”, and r means “cancel reservation”. Here, one can cancel the reservation only after the decision about the journey.

A direct comparison with the perfect model semantics for disjunctive programs is not possible, because unfolding can destroy a stratification in the case of disjunctive programs. For non-disjunctive programs, this obviously cannot happen.

**Example 5.2 (GPPE destroys stratification).** Consider the following stratified program:

\[
\begin{align*}
p & \leftarrow q. \\
p & \leftarrow \text{not } q. \\
q \lor r.
\end{align*}
\]

It has two perfect (Herbrand) models, namely \( I_1 := \{p, q\} \) and \( I_2 := \{p, r\} \).

But now consider what happens if we apply GPPE to the body literal q in the first rule:

\[
\begin{align*}
p \lor r. \\
p & \leftarrow \text{not } q. \\
q \lor r.
\end{align*}
\]

This logic program is not stratified. If we nevertheless naively try to apply the definition of the perfect model, we find that this program has no perfect model.

The stable model semantics does not have these problems. \( I_1 \) and \( I_2 \) are the two stable models of the first as well as the second program.

### 5.3. Relation to static semantics

Przymusinski's static semantics [49] is defined for arbitrary theories in the autoepistemic logic of beliefs (AEB). This is a much larger class than the class of disjunctive logic programs. However, we conjectured for quite some time that the static semantics would be equivalent to our D-WFS on the restricted domain of disjunctive logic programs and pure ground disjunctions as consequences (with each negative literal \( \neg A \) translated to \( \mathcal{B}(\neg A) \)). For instance, the static semantics never directly assumes a disjunction of belief literals – \( \mathcal{B}(\neg p) \lor \mathcal{B}(\neg q) \) follows from a disjunctive
logic program under the static semantics if and only if already $\mathcal{B}(\neg p)$ or $\mathcal{B}(\neg q)$ follows by itself. In this way, the static semantics behaves very similarly to our D-WFS. Of course, in more general belief theories it is possible to express the exclusive or in the form $\mathcal{B}(\lor \neg q)$.

But even for the restricted class of belief theories and queries corresponding to disjunctive logic programs it turned out that D-WFS is strictly weaker than the static semantics (the failure of our conjecture was first noted by Przymusinski).

**Example 5.3.** Consider the following logic program:

\[
\begin{align*}
p \lor q. \\
q \lor r. \\
s \leftarrow \text{not } p. \\
s \lor t \leftarrow \text{not } r.
\end{align*}
\]

This program is a residual program, so in particular not $t$ does not follow under our D-WFS. However, it does follow under the static semantics: in all minimal models, $p$ and $r$ are either both true or both false. So the static semantics implies $(\text{not } r) \implies (\text{not } p)$. But with this implication it becomes clear that $t$ never needs to be true in any minimal model, because if not $r$ is true, then not $p$ and therefore $s$ are also true.

However, the static semantics allows our transformations (if the possible consequences are restricted to pure positive and pure negative disjunctions, see above). So D-WFS can at least be seen as an approximation of the static semantics: if $Q \in \text{D-WFS}(P)$, then $Q$ is also contained in the least static expansion of $P$. The relation to the static semantics is more thoroughly investigated in Ref. [8].

5.4. Relation to GCWA

The generalized closed world assumption GCWA [44] is defined only for positive programs (disjunctive programs without negative body literals). Again, for our transformations this is no problem, because if they are applied in the “forward direction”, they never introduce new negative literals. It is easy to see that the GCWA allows all our transformations: as the GCWA looks only at minimal models, it satisfies unfolding, elimination of tautologies and elimination of non-minimal rules by Theorem 4.2. Positive and negative Reduction are trivially satisfied, because they are never applicable for positive programs. By Corollary 4.3, this means that $\text{GCWA}(P) = \text{GCWA}(\text{res}(P))$, where $\text{res}(P)$ is a set of minimal positive disjunctions. It is easy to see that GCWA in this case agrees with D-WFS:

**Theorem 5.4 (D-WFS extends GCWA).** Let $P$ be a positive program and $Q$ be a negative ground literal. Then we have

\[Q \in \text{D-WFS}(P) \iff Q \in \text{GCWA}(P).\]

Why do we require $Q$ being a negative literal and not an arbitrary pure disjunction? The original definition of GCWA in Ref. [44] only declares a set of certain negative literals to be derivable. The set of derivable positive disjunctions is taken as those that are true in all minimal models (see Section 4.2). Therefore our theorem remains true if $Q$ is any positive ground disjunction.
Can we also compute negative pure disjunctions other than just negative literals? For example, it makes sense to derive \( \neg p \lor \neg q \) from the program \( p \lor q \) because \( \neg p \lor \neg q \) holds in all minimal models. In fact, this is called the EGCV IA \[40\]. Although we do not follow this idea here, it is quite simple to use the residual program for computing EGCV IA. We just declare all those \( \neg A_1 \lor \cdots \lor \neg A_n \) to be derivable, such that \( A_1 \lor \cdots \lor A_n \) is subsumed by a clause in \( \text{res}(P) \).

5.5. A weak version of the disjunctive WFS

D-WFS as well as GCWA allow the elimination of non-minimal rules. For instance, in the program

\[
\begin{align*}
p \lor q. \\
p. 
\end{align*}
\]

it is possible to remove the first disjunction and to conclude \( \neg q \). It has been argued that some applications need a really inclusive interpretation of \( "\lor" \), so that the negation of ground atom \( A \) should not be assumed if \( A \) appears in the head of an applicable rule. For such applications, the "weak GCWA" was defined \[52,50\]. It is possible to define a similar version of our D-WFS, which we call WD-WFS. We simply replace the reduction operator \( R \) by a weaker version which does not remove non-minimal conditional facts.

**Definition 5.1 (Weak reduction operator).** For any set \( \Gamma \) of conditional facts, let

\[
R_{\text{weak}}(\Gamma) := \{ \mathcal{A} \leftarrow \neg (\mathcal{G} \cap \text{heads}(\Gamma)) \mid \mathcal{A} \leftarrow \neg \mathcal{G} \in \Gamma, \text{ and there is no } \mathcal{A}' \leftarrow \text{true} \in \Gamma \text{ with } \mathcal{A}' \subseteq \mathcal{G} \}.
\]

As is the case for the original reduction operator \( R \), the total number of atoms occurring in \( \Gamma \) is reduced in each step so that the whole process must come to an end after finitely many steps.

**Definition 5.2 (Weak residual program).** Let \( P \) be any logic program, and let \( \Gamma_0 := \text{lfp}(T_P) \), \( \Gamma_i := R_{\text{weak}}(\Gamma_{i-1}) \), and \( n \in \mathbb{N} \) with \( \Gamma_n = \Gamma_{n-1} \). Then we call \( w\text{-res}(P) := \Gamma_n \) the weak residual program of \( P \).

**Definition 5.3 (WD-WFS).** The semantics WD-WFS is defined by:

\[
\text{WD-WFS}(P) := \text{known}(w\text{-res}(P)).
\]

So this is only an operational definition of WD-WFS. It might seem at first that WD-WFS can be characterized as the weakest semantics which allows unfolding, elimination of tautologies, and positive and negative reduction. However, it turns out that WD-WFS as well as WGCWA do not allow the elimination of tautologies:

\[
\begin{align*}
p \lor q &\leftarrow p. \\
p &\leftarrow p.
\end{align*}
\]

Here the first rule is a tautology, but it is important for WD-WFS and WGCWA, because it blocks the assumption of the negation \( \neg q \).
The elimination of tautologies is used to show the equivalence of \( \text{lfp}(T_P) \) to the original program, so Corollary 4.1 is not applicable to the WGCWA. However, it is easy to show directly \( \text{WGCWA}(P) = \text{WGCWA}(\text{lfp}(T_P)) \). Since the reduction operator does nothing for positive programs, we get immediately the following theorem.

**Theorem 5.5 (WD-WFS extends WGCWA).** Let \( P \) be a positive program and \( Q \) be a positive ground disjunction or negative ground literal. Then we have \( Q \in \text{WD-WFS}(P) \iff Q \in \text{WGCWA}(P) \).

WD-WFS also agrees with the well-founded semantics on non-disjunctive programs. This shows, that in order to compute the well-founded model, it is not necessary to eliminate non-minimal rules.

**Corollary 5.4 (Computation of WFS).** Let \( P \) be any non-disjunctive program.

1. For every positive ground literal \( A \):
   \[ A \in \text{WFS}(P) \iff (A \leftarrow \text{true}) \in \text{w-res}(P). \]

2. For every negative ground literal \( \neg A \):
   \[ \neg A \in \text{WFS}(P) \iff A \notin \text{heads}(\text{w-res}(P)). \]

Let \( \leftrightarrow := \leftrightarrow_U \cup \leftrightarrow_T \cup \leftrightarrow_P \cup \leftrightarrow_N \). From Theorem 4.1 and Definition 1 it immediately follows that \( P \leftrightarrow \text{w-res}(P) \) for every ground program \( P \). However, this rewriting system does not have the nice confluence property: from the program

\[ \begin{align*}
  & p \leftarrow p \land \neg q.
  & p.
\end{align*} \]

we can get to the two irreducible programs \( P_1 = \{p\} \) and \( P_2 = \{p, p \leftarrow \neg q\} \) (and \( P_2 \) would be the weak residual program).

6. **Computational properties**

In this section, we will make a few short comments on the computational aspects of our approach. We have investigated the computation of the residual program in more detail in Ref. [3] for disjunctive programs and in Ref. [13] for non-disjunctive programs.

It seems that every query evaluation algorithm which is able to handle non-stratified programs has to delay negative ground literals under certain conditions. For instance, this is done in Refs. [20–23]. We believe that it is an important feature of our approach that such delaying and the whole computation can be understood on the source code level. Of course, specialized data structures can be useful for improving the efficiency, but they are not necessary for understanding the correctness of the method.

Our algorithm has a strong relation to the classical alternating fixpoint procedure, which was used in Ref. [43] for bottom-up computation of the (non-disjunctive) WFS. More precisely, they restrict the conditional facts to the head literal and a
one bit indication whether there is a non-trivial body or not. This is done by managing two versions of every predicate: the certainly true facts and the possibly true facts. Of course, this is a loss of information, but it can be compensated by recomputing the conditional facts for every step of the reduction phase. In Ref. [43], also the optimization is used that they start with the computation of certainly true facts, and then the first computation of the possibly true facts can be combined already with the first reduction.

Even for non-disjunctive programs, there can be exponentially many derivable conditional facts in some rare circumstances. Since it is known that the WFS can be computed in polynomial time, it is not acceptable to compute the complete residual program first. However, if the residual program is only used as an intermediate step for computing stable models, the possible exponential growth is not a big problem, since already for non-disjunctive programs, the stable semantics is NP-complete. A solution for avoiding the exponential growth, invented by Chen and Warren for their SLG-resolution [20–23], is to delay not only negative literals, but also positive literals which depend on already delayed negative literals. This idea has been adapted to our approach, and a practical algorithm for computing the well-founded model of non-disjunctive programs has been presented in Refs. [16,60]. The algorithm consists in applying our transformations positive and negative reduction, success, failure, and a Loop-Detection Rule (which is a special case of GPPE). All these transformations are of linear complexity and the corresponding algorithm is provably better than Van Gelder’s alternating fixpoint operator. We consider it as an interesting result that our framework also lead us to such an efficient algorithm.

It is interesting that positive and negative Reduction and the corresponding operators for the evaluation of delayed positive body literals in trivial cases (“success” and “failure”) exactly correspond to the least fixpoint of Fitting’s \( \Phi_p \) operator (see Theorem 2.3) used in some implementations of the WFS [46,55]. It must be noted, however, that delaying positive literals leads to the problem of positive loops, and current solutions are neither elegant nor very efficient. In the approach presented here, this problem simply does not occur.

An important optimization of our approach is to interleave the computation of derived conditional facts with the reductions. If we know already that a ground atom \( A \) is true, it is not necessary to derive a conditional fact containing \( \neg A \). If we know already that \( A \) is false, we can immediately evaluate \( \neg A \) to true, i.e. it is not necessary to delay the body literal. The number of ground atoms we know already to be true or false can be improved by ordering the computation according to the predicate dependencies. It is possible to compute the residual program locally for every strongly connected component of the program. For instance, for non-disjunctive stratified programs, it is never necessary to actually delay any negative body literal (as in the standard approach). It follows from our confluence results that optimizations changing the order of the application of the transformations are possible.

Finally, as for any bottom-up algorithm, we need some variant of the magic-set rewriting technique to make it goal-directed. For non-disjunctive programs this should not be very difficult, for disjunctive programs this is currently under research. However, it depends on the semantics whether such a transformation is possible at all. For instance, the STABLE semantics violates the “relevance” property [33,5], so in general, a goal-directed computation is not possible.
7. Conclusions

In this paper, we have presented a general approach to define semantics for disjunctive logic programs simply by postulating some properties. Although we applied this framework to a particular set of transformations, our method is not restricted to these: we can also handle comp3, WFS\textsubscript{C}, STABLE and WGCWA (see Section 2.4). In Refs. [34,35,2] still more transformation-rules are investigated.

The resulting semantics D-WFS turned out to be interesting, because it extends WFS and GCWA, and because of its strong relation to Przymusinski's static semantics, and the similarity to Ross's S-WFS. Furthermore, D-WFS is weaker than the disjunctive stable model semantics, so it gives no insensible conclusions.

Besides the abstract definition of our semantics, we were also able to develop a bottom-up query evaluation algorithm for it. It is important to note that although our definition of Partial Evaluation was given on instantiated programs, our bottom-up procedure works on non-ground programs. Our computation of the residual program uses only the given semantical properties and can also be used for other semantics having these properties (e.g. the disjunctive stable semantics and the static semantics).

In fact, we proved that the validity of this computation is equivalent to the given semantical properties, which is an astonishing result: it was not clear from the beginning, that a particular bottom-up procedure can be linked to a set of declarative transformation rules.

Our approach is based on the notion of conditional facts, developed independently by Bry and Dung and Kanchansut. The delaying of negative body literals is also implicit in many query evaluation algorithms. It is nice that we can do this on the level of programs, and not on the level of implementational data-structures: we believe that such an approach greatly enhances the general understanding of the algorithms. Once the details are hidden in low-level data-structures, a real understanding is much more difficult.

As a byproduct of our approach, we have a characterization of the standard WFS as the weakest semantics allowing unfolding (GPPE), elimination of tautologies, and positive and negative reduction. Similar results hold for GCWA, STABLE, WFS\textsubscript{C} and comp3. In fact, suitable subsets of our transformations can be applied directly to programs to compute a residual program in a very efficient way (for WFS and comp3). Queries can then be answered immediately from the residual program by using the identity in Definition 2.5. The underlying reason for this is the confluence of these calculi: a topic which is not investigated in this article (see Ref. [6]).

A simple prototype of our approach is available.\footnote{ftp://ftp.informatik.uni-hannover.de/software/index.html} Of course, the algorithm can be further optimized, this is subject of our future research. We are also interested to apply this framework to other semantics, and have already some results for the disjunctive stable semantics [3].

Last but not least we thank the anonymous referees for valuable comments and useful hints.

Appendix A. Proofs of theorems from Section 3

Proof of Lemma 3.2.

1. Because of the allowedness, the variables are completely instantiated in the computation of conditional facts. So the same conditional facts are computed based on $P$ and on $\text{ground}(P)$. Therefore, the input to the second phase of the computation is the same, so the resulting residual program is also identical.

2. The possibility of right weakening is obvious from the definition.

3. Let $\mathcal{A} \leftarrow \text{true}$ be in $P$. Then it is also contained in $\text{lfp}(T_p)$ and the only reason why it might not be in the resulting residual program is that there is a disjunctive fact $\mathcal{A}' \leftarrow \text{true}$ in the residual program with $\mathcal{A}' \subseteq \mathcal{A}$. In both cases we get $\mathcal{A} \in \mathcal{S}_{\text{res}}(P)$.

4. Let $A$ be a $\Xi$-ground atom with $A \notin \text{heads}(P)$. The derived disjunctive facts can contain only head literals already present in $P$, so $A \notin \text{heads}(\text{lfp}(T_p))$. The reduction operations also introduce no new head literals, and we get $A \notin \text{heads}(\text{res}(P))$. But this means that $\text{not } A \in \mathcal{S}_{\text{res}}(P)$.

Proof of Lemma 3.3. The proof is by induction on the number of applications $n$ of the operator $R$ to compute $\text{res}(\Gamma)$. However, we need to prove a slightly stronger induction hypothesis, namely in addition to $\text{res}(\Gamma) = \text{res}(\Gamma')$ we also prove that $\Gamma'$ never needs more reduction steps than $\Gamma$.

There is nothing to prove for $n = 0$, because if $\text{res}(\Gamma) = \Gamma$, then there is no $\Gamma'$ with $\Gamma \leftarrow_{\text{MPN}} \Gamma'$. Let us assume in the following that $\text{res}(\Gamma) \neq \Gamma$.

For the inductive step, we first show that $\Gamma \leftarrow_{\text{MPN}} \Gamma'$ implies $R(\Gamma) \leftarrow_{\text{MPN}}^{*} R(\Gamma')$:

1. Suppose that $\Gamma \leftarrow_{M} \Gamma'$ and that the conditional fact $\mathcal{A} \leftarrow \text{not } \mathcal{C}$ was deleted. If we apply the reduction operator once, $\mathcal{A} \leftarrow \text{not } \mathcal{C}$ is of course deleted. Otherwise $R(\Gamma)$ and $R(\Gamma')$ agree, except that $\text{heads}(\Gamma) \supset \text{heads}(\Gamma')$ might hold because of the additional rule $\mathcal{A} \leftarrow \text{not } \mathcal{C}$ in $\Gamma$. This means that the only difference between $R(\Gamma)$ and $R(\Gamma')$ is that some negative body literals have not been evaluated to true because they occurred in $\mathcal{A}$. Therefore, we have $R(\Gamma) \leftarrow_{M}^{*} R(\Gamma')$.

2. Let $\Gamma \leftarrow_{N} \Gamma'$ and let the body literal $\text{not } A$ with $A \notin \text{heads}(\Gamma)$ be evaluated to true in $\mathcal{A} \leftarrow \text{not } \mathcal{C}$. Obviously, $\text{not } A$ is also evaluated to true by the operator $R$. There are only two possibilities why $R(\Gamma)$ and $R(\Gamma')$ might differ: First, the rule $\mathcal{A} \leftarrow \text{not } (\mathcal{C} - \{\text{not } A\})$ can eliminate more non-minimal rules than $\mathcal{A} \leftarrow \text{not } \mathcal{C}$. Second, if $\mathcal{C} = \text{not } A$, it is possible that in $R(\Gamma')$ rules are deleted containing $\mathcal{A}'$ in the body. Thus, we again have $R(\Gamma) \leftarrow_{M}^{*} R(\Gamma')$.

3. Let $\Gamma \leftarrow_{X} \Gamma'$ and let $\mathcal{A} \leftarrow \text{not } \mathcal{C}$ be deleted because of $\mathcal{A}' \leftarrow \text{true}$. Of course, the first application of the reduction operator also deletes $\mathcal{A} \leftarrow \text{not } \mathcal{C}$, but as in the first case, it is possible that $\text{heads}(\Gamma) \supset \text{heads}(\Gamma')$. Thus we again have $R(\Gamma) \leftarrow_{M}^{*} R(\Gamma')$.

So now we have $R(\Gamma) \leftarrow_{M}^{*} R(\Gamma')$. Let $\Gamma_0 := R(\Gamma)$, $\Gamma_{i-1} \leftarrow_{M}^{*} \Gamma_i$, and $\Gamma_m = R(\Gamma')$. By applying the induction hypothesis the first time, we get $\text{res}(\Gamma_0) = \text{res}(\Gamma_1)$ and that $\Gamma_1$ does not need more reduction steps than $\Gamma_0$. So we can apply the induction hypothesis iteratively and finally get $\text{res}(\Gamma_0) = \text{res}(\Gamma_1) = \cdots = \text{res}(\Gamma_m)$, and thus $\text{res}(\Gamma) = \text{res}(\Gamma')$. 
By applying the inductive hypothesis iteratively, we also get that $F_\alpha = R(F')$ does not need more applications of $R$ than $F_0 = R(F)$. Since $R(F) = F$ is excluded, we have also proven the second half of the inductive proposition. □

**Proof of Lemma 3.4.** Let $\Delta_1 \subseteq \Delta_2$ and let $Q \in D_F(\Delta_1)$.

1. If $Q$ is a positive disjunction, this means there is $x \not\subseteq \Delta_1$ such that $\Delta_1 \subseteq \Delta_1^-$ holds. But then also $\Delta_1 \subseteq \Delta_1^-$ holds.

2. If $Q$ is a negative disjunction, this means that there is not $A \in Q$ such that for every $x \not\subseteq \Delta_1$ (at least) one of the following two cases holds:
   - There is $x' \in \Delta_1^+$ with $x' \not\subseteq A$. But then also $x' \not\subseteq A$ holds.
   - There is $x' \not\subseteq A$ with $x' \not\subseteq A$ and $(\Delta_1^+ - \Delta_1^-) \subseteq (\Delta_1^+ - \Delta_1^-)$, i.e. for every $A' \in \Delta_1^+$ with $A' \not\subseteq \Delta_1^+$, we have $A' \not\subseteq \Delta_1$. But this condition gets only weaker if we replace $\Delta_1$ by the superset $\Delta_2$. □

**Proof of Theorem 3.1.** Let $\Gamma_0 := \emptyset$ and $\Gamma_{i+1} := \Gamma/\text{known}(\Gamma_i)$. Obviously, we have that $\Gamma_{i+1} = \Gamma/\text{known}(\Gamma_i)$.

But then it is clear that the number of occurring literals decreases in every step, so we must get a $\Gamma_n$ which is irreducible with respect to $\rightarrow_{MPN}$, so $\Gamma_{n+1} = \Gamma_n$. By Lemma 3.3, we have $\text{res}(\Gamma) = \text{res}(\Gamma_n)$. Since $\Gamma_n$ is irreducible, we have $\text{res}(\Gamma_n) = \Gamma_n$. It follows that $\text{res}(\Gamma) = \Gamma_n$ and thus $\mathcal{S}_{\text{res}}(P) = \text{known}(\Gamma_n)$.

The standard construction of lfp($D_F$) is (in this finite case): $\Delta_0 := \emptyset$, $\Delta_{i+1} := \text{known}(\Gamma/\Delta_i)$ until a fixpoint is reached. This means that $\Gamma_i = \Gamma/\Delta_i$ and $\Delta_{i+1} = \text{known}(\Gamma_i)$ for all $i \geq 0$. But since $\Gamma_{n+1} = \Gamma_n$, this also means $\Delta_{n+2} = \Delta_{n+1}$, so lfp($D_F$) = $\Delta_{n+1} = \text{known}(\Gamma_n) = \text{known}(\text{res}(\Gamma))$. This proves $\mathcal{S}_{\text{res}}(P) = \text{lfp}(D_F)$.

Since $\Gamma_{n+1} = \Gamma/\text{known}(\Gamma_n) = \Gamma_n = \text{res}(\Gamma)$, and $\text{known}(\Gamma_n) = \text{lfp}(D_F)$, it follows that $\text{res}(\Gamma) = \Gamma/\text{lfp}(D_F)$. □

**Appendix B. Proof of Theorem 4.1.**

Our goal is to show that it is possible to reach lfp($T_P$) from $P$ by a series of unfolding, weak unfolding and “elimination of tautology”-steps. The proof would be much simpler if we did not care about non-minimal conditional facts. However, since this restriction is not needed, and there are semantics, for which non-minimal rules are relevant, we prove the stronger and more elegant result. Let us first look at some examples to illustrate the problems.

**Example B.1.** We once hoped that if $P'$ results from $P$ by unfolding, then lfp($T_P$) = lfp($T_{P'}$). This, however, does not hold. Let $P$ be:

- $p \lor q \leftarrow r$.
- $r \leftarrow q$.
- $q \lor r$.

For this program, we get lfp($T_P$) = $\{q \lor r, p \lor q, r, p \lor r\}$. Now if we unfold $r$ in the first rule, we replace this rule by

- $p \lor q \leftarrow q$.
- $p \lor q$.

Note that $p \lor q \leftarrow q$ is a tautology, and in fact, this tautology is the source of the problem: with it we can derive $p \lor q \lor r$ which is not in lfp($T_P$).
Example B.2. In the above example, it would have been possible to simply eliminate the tautology before further unfolding steps in order to avoid the derivation of the critical conditional fact. But this is not always correct, because if the program \( P \) itself contains a tautology, e.g.

\[
p \lor q \leftarrow q.
\]

\[
q \lor r.
\]

then we of course have to apply the tautology to get the conditional fact \( p \lor q \lor r \) contained in \( \text{lfp}(T_p) \).

Example B.3. In fact, tautologies can also occur as intermediate results because unfolding in contrast to hyperresolution evaluates only one body literal at a time. Consider for example the following program:

\[
p \leftarrow q \land r.
\]

\[
q \lor r.
\]

\[
r \lor s.
\]

If we unfold the first body literal, we get \( p \lor r \leftarrow r \). Then another application of GPPE yields \( p \lor r \lor s \), the result of hyperresolution.

Lemma B.1. Let \( P \) be a ground logic program containing the two rules

\[
\therefore \quad \therefore' \leftarrow \begin{cases} 
B_0 & \land \ B_1 \land \cdots \land B_m \land \not \in \gamma.
\end{cases}
\]

\[
B_0 \lor \therefore' \leftarrow \begin{cases} 
B'_1 \land \cdots \land B'_n \land \not \in \gamma'.
\end{cases}
\]

Let \( P' \) contain in addition the rule which would result from unfolding, i.e.

\[
P' := P \cup \{(\therefore \cup \therefore') \leftarrow B_1 \land \cdots \land B_m \land B'_1 \land \cdots \land B'_n \land \not \in (\gamma \cup \gamma')\}.
\]

If the added rule is not a tautology, then \( \text{lfp}(T_{P'}) \subseteq \text{lfp}(T_P) \).

Proof. To simplify the notation, we consider only the case without \( \gamma, \gamma' \). This is no real restriction, since negative body literals can be moved into the heads if they are distinguished by making their predicate symbols disjoint from the positive head and body literals.

Now let the \( \therefore \) \& \( \therefore' \) rule be applied to disjunctive facts \( \therefore_i, i = 1, \ldots, m \), and \( \therefore'_j, j = 1, \ldots, n \). Then the resulting disjunctive fact is

\[
\therefore \cup \therefore' \cup \bigcup_{i=1}^{m} (\therefore_i - \{B_i\}) \cup \bigcup_{j=1}^{n} (\therefore'_j - \{B'_j\}).
\]

(\#)

Now we have to distinguish several cases to show that this conditional fact is also derivable in \( P \). Each case fills a hole in the preceding case.

1. The natural idea to derive this disjunctive fact would be to first apply the rule

\[
B_0 \lor \therefore' \leftarrow B'_1 \land \cdots \land B'_n \land \not \in \gamma.
\]

and get

\[
\{B_0\} \cup \therefore' \cup \bigcup_{j=1}^{n} (\therefore'_j - \{B'_j\}).
\]

We then enter this for \( B_0 \) into \( \therefore \leftarrow B_1 \land \cdots \land B_m \). This results in

\[
\therefore \cup (\therefore' - \{B_0\}) \cup \bigcup_{j=1}^{n} (\therefore'_j - \{B'_j, B_0\}) \cup \bigcup_{i=1}^{m} (\therefore_i - \{B_i\}).
\]
Of course, $\mathcal{A}'$ does not contain $B_0$, so this set-difference is effectless and $(\mathcal{A}' - \{B_0\})$ can be simplified to $\mathcal{A}'$. However, we have to assume that the $\mathcal{A}'_j$, $j = 1, \ldots, n$, do not contain $B_0$ (or that $B_0 = B_0$) in order to really get $(\ast)$. This hole is treated in case 2.

2. Now we assume that $B_0 \in \mathcal{A}'_j$ and $B_0 \neq B_j$ for at least one $1 \leq j \leq n$. Without loss of generality, we can choose $j = 1$ to simplify the notation. Then we first apply the rule $\mathcal{A} \leftarrow B_0 \land B_1 \land \cdots \land B_n$ and enter $\mathcal{A}'_1$ for the body literal $B_0$. This results in

$$\mathcal{A} \cup (\mathcal{A}'_1 - \{B_0\}) \cup \bigcup_{i=1}^m (\mathcal{A}_i - \{B_i\}).$$

Since $B_0 \neq B'_1$, the generated disjunctive fact contains $B'_1$. Therefore, we can insert it into $B_0 \lor \mathcal{A}' \leftarrow B'_1 \land \cdots \land B'_n$. This gives

$$\{B_0\} \cup \mathcal{A}' \cup (\mathcal{A}' - \{B'_1\}) \cup (\mathcal{A}'_1 - \{B_0, B'_1\}) \cup \bigcup_{i=1}^m (\mathcal{A}_i - \{B_i, B'_1\}) \cup \bigcup_{i=2}^n (\mathcal{A}'_i - \{B'_i\}).$$

Now let us check that this is equivalent to $(\ast)$. First, $\{B_0\} \cup (\mathcal{A}'_1 - \{B_0, B'_1\})$ can be simplified to $\mathcal{A}'_1 - \{B'_1\}$, since $B_0 \in \mathcal{A}'_1$ and $B_0 \neq B'_1$. Second, $\mathcal{A}'$ cannot contain $B'_1$, since otherwise the combined rule would be a tautology. However, we have to assume now that $B'_1 \notin \mathcal{A}'$, or $B'_1 = B_i$ for $i = 1, \ldots, m$ (otherwise see case 3). Then the above expression is equivalent to $(\ast)$.

3. The current situation is as follows: $B_0 \in \mathcal{A}'_j$ and $B_0 \neq B_j$ for at least one $1 \leq j \leq n$, furthermore $B'_j \in \mathcal{A}'_j$, and $B'_j \neq B_j$ for at least one $1 \leq i \leq n$. Again, without loss of generality, we can choose $j = 1$ and $i = 1$. Then we first enter $\mathcal{A}'_1$ for $B'_1$ in the rule $B_0 \lor \mathcal{A}' \leftarrow B'_1 \land \cdots \land B'_n$. This results in

$$\{B_0\} \cup \mathcal{A}' \cup (\mathcal{A}'_1 - \{B'_1\}) \cup \bigcup_{i=1}^m (\mathcal{A}_i - \{B_i\}).$$

Since $B'_1 \neq B_1$, the generated disjunctive fact contains $B_1$. Therefore, we can insert it for $B_1$ in the rule $\mathcal{A} \leftarrow B_0 \land B_1 \land \cdots \land B_n$, and insert $\mathcal{A}'_1$ for $B_0$. The result is

$$\mathcal{A} \cup (\mathcal{A}'_1 - \{B_0\}) \cup (\{B_0\} - \{B_1\}) \cup (\mathcal{A}' - \{B_1\}) \cup (\mathcal{A}'_1 - \{B'_1, B_1\}) \cup \bigcup_{i=2}^m (\mathcal{A}_i - \{B_i\}) \cup \bigcup_{i=2}^n (\mathcal{A}'_i - \{B'_i\}).$$

Now let us check that this is indeed equivalent to $(\ast)$. First, we allow no duplicate body literals, so $B_0 \neq B_1$, therefore the term $\{B_0\} - \{B_1\}$ entails that $B_0$ is contained in the result, and we already know that it is also contained in $(\ast)$. Second, we have $\mathcal{A}'_1 - \{B_0\}$ instead of $\mathcal{A}'_1 - \{B'_1\}$. But the result already contains $B_0$, so the set-difference has no effect on the total result, and $(\ast)$ also contains $B'_1$ (because $B'_1 \in \mathcal{A}'_1$ and $B'_1 \neq B_1$), so it is correct that the result contains $B'_1$ (since $B'_1 \neq B_0$). Third, $\mathcal{A}'$ cannot contain $B_1$, since otherwise the combined rule would be a tautology. Fourth, we eliminate $B'_1$ from $\mathcal{A}'_1$, but it is still contained in the result as explained above. Finally, we have to assume that $B_1 \notin \mathcal{A}'_1$ (or else $B_1 = B'_j$ for $j = 2, \ldots, n$ (see case 4).

4. Now, the remaining little hole can be described as follows: as in case 3, we have $B_0 \in \mathcal{A}'_1$, $B_0 \neq B'_1$, and $B'_1 \in \mathcal{A}'_1$, $B'_1 \neq B_1$. Now in addition, there is a $2 \leq j \leq n$, with $B_1 \in \mathcal{A}'_j$ and $B_1 \neq B'_j$. To simplify the notation, we choose $j = 2$. In this case, we
first apply the rule $\mathcal{A} \leftarrow B_0 \land B_1 \land \cdots \land B_m$ and insert $\mathcal{A}'$ for $B_0$ and $\mathcal{A}''$ for $B_1$. This results in

$$
\mathcal{A} \cup (\mathcal{A}' - \{B_0\}) \cup (\mathcal{A}'' - \{B_1\}) \cup \bigcup_{i=2}^{m}(\mathcal{A}_i - \{B_i\}).
$$

Now we apply the rule $B_0 \lor \mathcal{A}' \leftarrow B_1' \land \cdots \land B_n'$ and insert $\mathcal{A}_1$ for $B_1'$ and the above constructed disjunctive fact for $B_2'$. (Since $B'_2 \neq B_1$, the constructed disjunctive fact really contains $B'_2$.) The result is

$$
(\mathcal{A}_0 \cup \mathcal{A}'' \cup \mathcal{A}_1 \cup (\mathcal{A}' - \{B_1'\}) \cup (\mathcal{A}'' - \{B_2'\}))
\cup (\mathcal{A}'_i - \{B_0, B'_2\}) \cup (\mathcal{A}''_j - \{B_1, B'_2\})
\cup \bigcup_{i=2}^{m}(\mathcal{A}_i - \{B_i, B'_2\}) \cup \bigcup_{j=3}^{n}(\mathcal{A}'_j - \{B'_j\}).
$$

Now the result contains
- $B_0$,
- $B_1$, since $B_1 \in \mathcal{A}_1$ and $B'_1 \neq B_1$,
- $B'_1$ since $B'_1 \in \mathcal{A}'_1, B_0 \neq B'_1$ and $B'_2 \neq B_1'$ (we allow no duplicate body literals).

So set-differences with these atoms have no effect. Next, $\mathcal{A} - \{B'_2\} = \mathcal{A}$, since $B'_2 \in \mathcal{A}$ would make the combined rule a tautology. By applying these simplifications, we get:

$$
(\mathcal{A}_0 \cup \mathcal{A}' \cup \mathcal{A}_1 \cup (\mathcal{A}'_i - \{B'_1\}) \cup (\mathcal{A}''_j - \{B'_2\}))
\cup \bigcup_{i=2}^{m}(\mathcal{A}_i - \{B_i, B'_2\}) \cup \bigcup_{j=3}^{n}(\mathcal{A}'_j - \{B'_j\}).
$$

Note that also $(*)$ contains
- $B_0$ (since $B_0 \in \mathcal{A}'$ and $B_0 \neq B'_1$),
- $B_1$ (since $B_1 \in \mathcal{A}'_1$ and $B_1 \neq B'_2$), and
- $B'_1$ (since $B'_1 \in \mathcal{A}'_1$ and $B'_1 \neq B_1$).

Therefore, in order to get from the above expression to $(*)$, we only need the following assumptions: $B'_2 \notin \mathcal{A}$ and $B'_2 \notin \mathcal{A}_1$ (or $B'_2 = B_i$) for $i = 2, \ldots, m$ (otherwise see case 5).

5. The current situation is as follows: The resulting disjunctive fact $(*)$ contains
- $B_0$ (because $B_0 \in \mathcal{A}'$ and $B_0 \neq B'_1$),
- $B'_1$ (because $B'_1 \in \mathcal{A}'_1, B_0 \neq B'_1$),
- $B_1$ (because $B_1 \in \mathcal{A}'_2, B_1 \neq B'_2$), and
- $B'_2$ (because either $B'_2 \in \mathcal{A}'_1$, $B'_2 \neq B_1'$, or $B'_2 \in \mathcal{A}_1$, $2 \leq i \leq m, B'_2 \neq B_i'$).

If we apply the rules as in case 1 (i.e. in the most natural way), our only risk is to lose $B_0$. Let the result be $\mathcal{A}'_1$. Next, we apply the rules as in case 3. This time, we may lose $B_1$. Let the result be $\mathcal{A}'_2$. Since $B_0 \neq B'_1, \mathcal{A}'_1$ contains $B'_1$, and since $B_1 \neq B'_2, \mathcal{A}'_2$ contains $B'_2$. Therefore, we can insert $\mathcal{A}'_1$ and $\mathcal{A}'_2$ for $B'_1$ and $B'_2$ into $B_0 \lor \mathcal{A}' \leftarrow B'_1 \land B'_2 \land \cdots \land B_n'$. The result surely contains $B_0$, and also $B_1$ (from $\mathcal{A}'_1 - \{B'_1\}$), as well as $B'_1$ (from $\mathcal{A}'_2 - \{B'_2\}$), and $B'_2$ (from $\mathcal{A}_1 - \{B_1\}$) or directly if $B'_2 = B_0$). The rest of $(*)$ was already contained in the intermediate result and simply carries through. \(\square\)

**Lemma B.2.** Let $P$ be an instantiated logic program containing a rule

$$
\mathcal{A} \leftarrow B_0 \land B_1 \land \cdots \land B_m \land \text{not } C
$$

and a conditional fact $B_0 \lor \mathcal{A}' \leftarrow \mathcal{C}'$. Let
\[ P' := P \cup \{(\mathcal{A} \cup \mathcal{A}') \leftarrow B_1 \land \cdots \land B_m \land \text{not } (\mathcal{C} \cup \mathcal{C}')\}. \]

Then $\text{lfp}(T_{P'}) \subseteq \text{lfp}(T_P)$.

**Proof.** This is trivial: if something is derivable using the new rule, then we can also use the old rule with the conditional fact. \[ \square \]

**Proof of Theorem 4.1.** We have to construct $\text{lfp}(T_p)$ from the ground instantiation of $P$ by using only unfolding, weak unfolding, and elimination of tautologies. Note that $\text{ground}(P)$ is finite because of our restrictions on $\Sigma$.

1. First, we apply weak unfolding until nothing changes. However, directly after every application of weak unfolding, we delete every newly generated tautology, which did not result from applying a conditional fact. Therefore, the added rules do not increase the set of derivable conditional facts by Lemma B.1 and Lemma B.2. This means in particular that all generated conditional facts are contained in $\text{lfp}(T_p)$.

   On the other hand, every conditional fact in $\text{lfp}(T_p)$ is generated: for instance, consider the rule $\mathcal{A} \leftarrow B_1 \land \cdots \land B_n \land \text{not } \mathcal{C}$ applied to conditional facts $\mathcal{A}_i \leftarrow \text{not } \mathcal{C}_i$. The result contained in $\text{lfp}(T_p)$ is
\[ \mathcal{A} \cup \bigcup_{i=1}^{n} (\mathcal{A}_i \setminus \{B_i\}) \leftarrow \text{not } (\mathcal{C} \cup \bigcup_{i=1}^{n} \mathcal{C}_i). \]

By applying GPPE to the first body literal, we get
\[ \mathcal{A} \cup (\mathcal{A}_1 \setminus \{B_1\}) \leftarrow B_2 \land \cdots \land B_n \land \text{not } (\mathcal{C} \cup \mathcal{C}_1). \]

Next, we apply GPPE to $B_2$ in this rule, and insert $\mathcal{A}'_2 \leftarrow \text{not } \mathcal{C}_2$. And so on.

2. Second, we delete all rules which still have positive body literals by applying unfolding. In order to do this, we first delete all tautologies (we also delete immediately any tautology which is later generated). Since there are no tautologies, unfolding some positive body literal generates only rules without this body literal. And once this body literal has vanished from all rules in the program, it can never be introduced again by unfolding. Therefore, all occurring positive body literals can be eliminated one after the other. Note also that no rules are created which are not already contained in the program due to the first phase. Therefore, the set of conditional facts does not increase, and after all other rules are eliminated, $\text{lfp}(T_p)$ remains. \[ \square \]

**Appendix C. Proofs of Lemmas 4.1 and 4.2, and Theorem 4.2**

**Proof of Lemma 4.1.** The immediate consequence operator $T_p$ for conditional facts is very similar to the hyperresolution operator. More specifically, it is identical in the case of positive logic programs. Let us define $\bar{P}$ for a logic program $P$ to be the positive logic program arising from the translation of every rule
\[ A_1 \lor \cdots \lor A_k \leftarrow B_1 \land \cdots \land B_m \land \text{not } C_1 \land \cdots \land \text{not } C_n \]

into
\[ A_1 \lor \cdots \lor A_k \lor \bar{C}_1 \lor \cdots \lor \bar{C}_n \leftarrow B_1 \land \cdots \land B_m. \]
where $C_i$ is an atom with a new predicate symbol. Now let $\Gamma := \text{lfp}(T_p)$, i.e. the disjunctive facts derivable by hyperresolution. Then the translation back into conditional facts gives exactly $\Gamma = \text{lfp}(T_p)$: Since the new atoms did not occur in any rule body, they did not participate in the resolution.

But for hyperresolution we know a correctness and completeness result, namely that it only computes disjunctive facts which are logical consequences of $\mathcal{P}$, and that it computes at least all minimal such disjunctive facts (minimal with respect to $\subseteq$ if we view such facts as sets of atoms): See, e.g., Ref. [12].

**Proof of Lemma 4.2.** So let $P_1 \cup P_2$ and suppose that unfolding was applied to the atom $B$ in the rule $\mathcal{A} \leftarrow (\mathcal{B} \cup \{B\}) \cup \text{not } C$.

In order to show that $P_1$ and $P_2$ have the same minimal models, we first show that a minimal model of $P_1$ is also a model of $P_2$ and vice versa:

- Let $I$ be a model of $P_1$ (we do not need the minimality in this direction). Since the combined rules are logical consequences of the old rules, $I$ is also a model of $P_2$.
- Let new $I$ be a minimal model of $P_1$. The only rule of $P_1$ which is not also contained in $P_2$ (and thus could be possibly violated) is $\mathcal{A} \leftarrow (\mathcal{B} \cup \{B\}) \cup \text{not } C$. Suppose that $I$ would violate this rule. Then every body literal including $B$ would be true in $I$ and every head literal would be false. Consider the interpretation $I_0$ with $I_0 \models B$, but which otherwise agrees with $I$. Since $I$ is a minimal model of $P_2$ and $I_0$ is smaller, $I_0$ cannot be a model of $P_2$. Since $I_0$ differs only in the truth value of $B$ from the model $I$ of $P_2$, it must violate a rule with $B$ in the head (remember that our models assign independent truth values to positive and negative literals, so the truth value of $\text{not } B$ is the same in $I$ and $I_0$). This rule must already be contained in $P_1$ (if it were one of the rules resulting from the unfolding step, we had $B \in \mathcal{A}$, contradicting the assumption that $I$ violates the unfolded rule). So the rule which $I_0$ violates is one of the rules about $B$ in $P_1$, say $\mathcal{A} \leftarrow \mathcal{B} \wedge \text{not } C$. This means that $\mathcal{B} \wedge \text{not } C$ is true in $I_0$ and thus in $I$. Furthermore $\mathcal{A} \wedge \text{not } C$ is false in $I_0$, and thus $\mathcal{A} \leftarrow \{B\}$ is false in $I$. But then $I$ violates the combined rule:

$$\mathcal{A} \cup (\mathcal{A} \leftarrow \{B\}) \leftarrow (\mathcal{B} \cup \mathcal{B}) \wedge (C \wedge \text{not } C).$$

This is impossible, since $I$ was assumed to be a model of $P_2$.

Now we show that the minimal models agree. We only show that a minimal model of $P_1$ is also a minimal model of $P_2$. The other direction is completely analogous with $P_1$ and $P_2$ interchanged.

Let $I$ be a minimal model of $P_1$. We have shown above that it is a model of $P_2$. If there were a smaller model $I'$ of $P_2$, there would also be a minimal model $I''$ of $P_2$ smaller than (or equal to) $I'$ and thus smaller than $I$. But as shown above, $I''$ would be a model of $P_1$, contradicting the assumed minimality of $I$. $\square$

**Lemma C.1.** Let $P_1$ and $P_2$ be distinct ground programs which are both irreducible with respect to unfolding and elimination of non-minimal rules. Then there is an interpretation which is a minimal model of one of these programs, but not of the other.

**Proof.** Since unfolding is not applicable to $P_1$ and $P_2$, they cannot contain rules with positive body literals. So $P_1$ and $P_2$ consist only of conditional facts. Since the
programs are distinct, there must be a conditional fact $\mathcal{A} \leftarrow \neg \mathcal{C}$, which is contained only in one program, but not in the other. It is possible to choose $\mathcal{A} \leftarrow \neg \mathcal{C}$ such that the other program does also not contain a conditional fact $\mathcal{A}' \leftarrow \neg \mathcal{C}'$ with $\mathcal{A}' \subseteq \mathcal{A}$ and $\mathcal{C}' \subseteq \mathcal{C}$ (if there were such a $\mathcal{A} \leftarrow \neg \mathcal{C}$, we would use it as the distinguishing conditional fact: the first program cannot contain $\mathcal{A}' \leftarrow \neg \mathcal{C}'$ with $\mathcal{C}' \subseteq \mathcal{C}$ and $\mathcal{A}' \subseteq \mathcal{A}$, since then $\mathcal{A}' \subseteq \mathcal{A}$ and $\mathcal{C} \subseteq \mathcal{C}'$ contradicting the irreducibility with respect to the elimination of non-minimal rules).

Without loss of generality let us assume that $P_1$ contains $\mathcal{A} \leftarrow \neg \mathcal{C}$, and $P_2$ does not contain any conditional fact $\mathcal{A} \leftarrow \neg \mathcal{C}$ with $\mathcal{A} \subseteq \mathcal{A}'$ and $\mathcal{C} \subseteq \mathcal{C}'$. Then let $I$ be the interpretation which $\neg \mathcal{C}$ true, all other negative literals false, and $\mathcal{A}$ false, and all other positive literals true. Obviously, $I$ is a model of $P_2$: if a conditional fact $\mathcal{A} \leftarrow \neg \mathcal{C}$ in $P_2$ were violated, it would satisfy $\mathcal{A} \subseteq \mathcal{A}'$ and $\mathcal{C} \subseteq \mathcal{C}'$, but such conditional facts do not occur in $P_2$.

Now let $I_0$ be a minimal model of $P_2$ smaller than (or equal to) $I$. But $I_0$ violates the conditional fact $\mathcal{A} \leftarrow \neg \mathcal{C}$ in $P_1$; the negative body literals are interpreted as in $I$, so $\neg \mathcal{C}$ is true, and the interpretation of the positive literals can only switch from true to false, so $\mathcal{A}$ remains false.

**Proof of Theorem 4.2**

1. Let $\mathcal{S}$ be a semantics which allows unfolding, elimination of tautologies and elimination of non-minimal rules. Further let $P_1$ and $P_2$ be any logic programs which have the same set of minimal models. For $i = 1, 2$, let $\Gamma_i := \text{llp}(T_P)$ and $\Gamma_i'$ result from $\Gamma_i$ by elimination of all non-minimal rules. Then $\text{ground}(P_i) \leftarrow \text{imod} \Gamma_i'$ by Theorem 4.1. Since minimal models are not changed by unfolding (Lemma 4.2), elimination of tautologies and elimination of nonminimal rules, $\Gamma_i'$ has the same minimal models as $\Gamma_1$ and $\Gamma_2$ has the same minimal models as $\Gamma_2$. But since $P_1$ and $P_2$ agree in their minimal models, so do $\Gamma_1'$ and $\Gamma_2'$. But then Lemma C.1 tells us that $\Gamma_1' = \Gamma_2'$. Since $\mathcal{S}$ also allows $\leftarrow \text{imod}$, we get $\mathcal{S}(P_1) = \mathcal{S}(\Gamma_1') = \mathcal{S}(\Gamma_2') = \mathcal{S}(P_2)$.

2. Suppose that $\mathcal{S}$ looks only at the minimal models of the programs. Then it obviously allows unfolding, elimination of tautologies, and elimination of nonminimal rules because these transformations do not change the set of minimal models of a program: for unfolding, this was proven in Lemma 4.2. The other transformations are equivalence transformations, which do not change the models at all.

**Appendix D. Proof of Theorem 4.3**

**Lemma D.1.** Let $P_1$ and $P_2$ be ground logic programs with $P_1 \leftarrow \text{imod} P_2$ (i.e. $P_2$ results from unfolding, weak unfolding, elimination of tautologies or elimination of non-minimal rules). Then $\text{res}(P_1) = \text{res}(P_2)$.

**Proof.** Let $\Gamma_1$ be the conditional facts derivable from $P_1$, i.e. $\Gamma_1 := \text{llp}(T_P)$, and $\Gamma_2$ be those derivable from $P_2$. In the case of unfolding, Lemma 4.2 tells us that $P_1$ and $P_2$ have the same minimal models. The other transformations $\leftarrow w, \leftarrow T, \leftarrow M$ are equivalence transformations and do not change the models at all. Then, by Lemma
4.1. $\Gamma_1$ and $\Gamma_2$ contain the same minimal conditional facts, although they might differ in non-minimal conditional facts (see Example B.1).

Let $\Gamma_0$ result from $\Gamma_1$ by removing all nonminimal facts. Then we obviously have $\Gamma_1 \leftarrow M_0$, and, as shown above, $\Gamma_2 \leftarrow M_0$. But now Lemma 3.3 gives us $\text{res}(\Gamma_1) = \text{res}(\Gamma_0) = \text{res}(\Gamma_2)$ and therefore $\text{res}(\Pi_1) = \text{res}(\Pi_2)$. □

**Proof of Theorem 4.3.** Lemma D.1 contains the proof for $\leftarrow U$, $\leftarrow W$, $\leftarrow T$, and $\leftarrow M$. So only positive and negative reduction are missing. Let $\Pi_1 \leftarrow N \Pi_2$ or $\Pi_1 \leftarrow P \Pi_2$.

Further, let $\Gamma_1 = \text{lfp}(\Pi_1)$ and $\Gamma_2 = \text{lfp}(\Pi_2)$. We show that then $\Gamma_1 \leftarrow N \Gamma_2$. resp. $\Gamma_1 \leftarrow P \Gamma_2$. The intuitive reason is that negative body literals are attached to every conditional fact which is derived using the rule directly or indirectly. So instead of evaluating it to true or false before the derivation of implied conditional facts, we can also evaluate it later in every resulting conditional fact.

1. Let $\Pi_1 \leftarrow N \Pi_2$ and let $\mathcal{A} \leftarrow \mathcal{B} \land \neg \mathcal{C}$ be the rule deleted because there is a disjunctive fact $\mathcal{A}' \leftarrow \text{true}$ in $\Pi_1$ with $\mathcal{A}' \subseteq \mathcal{A}$. It is easy to show by induction on the number $i$ of derivation steps that every conditional fact $\mathcal{A}'' \leftarrow \neg \mathcal{C}''$ in $T_{\Pi_1} \uparrow i$ is also satisfies $\mathcal{A}' \subseteq \mathcal{C}'$. On the other hand, we obviously have $T_{\Pi_2} \uparrow i \subseteq T_{\Pi_1} \uparrow i$. Therefore $\Gamma_1 \leftarrow N \Gamma_2$.

2. Let $\Pi_1 \leftarrow P \Pi_2$ and let $\neg \mathcal{C}$ be the negative literal evaluated to true. It is easy to show by induction on the number $i$ of derivation steps that for every conditional fact $\mathcal{A}_1 \leftarrow \neg \mathcal{C}_1$ in $T_{\Pi_1} \uparrow i$, either $\mathcal{A}_1 \leftarrow \neg \mathcal{C}_1$ or $\mathcal{A}_1 \leftarrow \neg \mathcal{C}_1 \cup \{\mathcal{C}\}$ or both appear in $T_{\Pi_2} \uparrow i$. Vice versa, for every conditional fact $\mathcal{A}_2 \leftarrow \neg \mathcal{C}_2$ in $T_{\Pi_1} \uparrow i$, either itself or $\mathcal{A}_2 \leftarrow \neg \mathcal{C}_2 \cup \{\mathcal{C}\}$ or both appear in $T_{\Pi_1} \uparrow i$. Therefore $\Gamma_1 \leftarrow P \Gamma_2$.

Now Lemma 3.3 yields $\text{res}(\Gamma_1) = \text{res}(\Gamma_2)$, and therefore $\text{res}(\Pi_1) = \text{res}(\Pi_2)$. □

**Proof of Lemma 4.3.** We show that for all ground programs $\Pi_1 \leftarrow \Pi_2$ and consistent interpretations $I$, if $I$ is a normal model of $\Pi_2$ then it is also a normal model of $\Pi_1$.

1. Elimination of tautologies and elimination of non-minimal rules and weak unfolding do not change the set of models, and unfolding does not change the set of minimal models by Lemma 4.2. Furthermore, these transformations never introduce new head literals, so the condition that atoms not occurring in the head must be interpreted as false can only become stronger (thus, if it is satisfied for $\Pi_2$, it is automatically satisfied for $\Pi_1$). Finally, disjunctive facts are only deleted if there still is a stronger disjunctive fact.

2. Now let us consider positive reduction and let $\mathcal{A} \leftarrow \mathcal{B} \land \neg \mathcal{C}$ be the rule deleted because there is a disjunctive fact $\mathcal{A}' \leftarrow \text{true}$ in $\Pi_1$ with $\mathcal{A}' \subseteq \mathcal{A}$. Positive reduction makes the rule stronger, so $I$ is certainly a model of $\Pi_1$. Since $C$ does not occur in any rule head in $\Pi_1$, we also have $C \notin \text{heads}(\Pi_2)$ and thus $I \models \neg \mathcal{C}$. But then, if there were a smaller model $I_0$ of $\Pi_1$, it would also satisfy $I_0 \models \mathcal{A} \land \neg \mathcal{C}$, and thus it would also be a model of $\Pi_2$ contradicting the assumed minimality of $I$.

As the above transformations, positive reduction can make the additional restrictions on the interpretation of negative literals only stronger.

3. Finally, suppose that $\Pi_2$ results from negative reduction and let $\mathcal{A} \leftarrow \mathcal{B} \land \neg \mathcal{C}$ be the rule deleted because there was a disjunctive fact $\mathcal{A}' \leftarrow \text{true}$ in $\Pi_1$ with $\mathcal{A}' \subseteq \mathcal{A}$. Since $I$ is a normal model of $\Pi_2$, and $\mathcal{A}' \subseteq \mathcal{C}$ is also contained in $\Pi_2$, we know that $I$ must make the negation of one of the atoms in $\mathcal{A}'$ false, and thus $I$ is automatically a
model of $P_1$. Furthermore, since $P_2 \subseteq P_1$, any smaller model of $P_1$ would also be a model of $P_2$ contradicting the minimality of $I$. Finally, by removing a rule (with non-empty body), the additional restrictions can only become stronger. By Corollary 4.2, we have $\text{ground}(P) \implies _{\text{WF}} \text{res}(P)$. Thus, we can show by induction on the length of the derivation that $I$ is also a normal model of $\text{ground}(P)$ (and thus $P$), where the above result is the inductive step. 

Proof of Theorem 4.4. We show that if $Q \in \mathcal{D-WFS}(P)$, then $P \cup \mathcal{D-WFS}(P) \not\models Q$. We do this by constructing a normal model $I$ of $\text{res}(P)$ with $I \not\models Q$.

1. Let $Q$ be a disjunction of negative ground literals: $\text{not } A_1 \lor \cdots \lor \text{not } A_n$. Since $Q \not\in \mathcal{D-WFS}(P)$, every $A_i$ appears in a rule head in $\text{res}(P)$. Let $I_0$ be the following interpretation:
   • $I_0 \models \text{not } A$ iff $A \not\in \text{heads}(\text{res}(P))$,
   • $I_0 \models A$ iff $A \in \text{heads}(\text{res}(P))$.

   Obviously, $I_0$ is a model of $\text{res}(P)$. Let $I$ be a minimal model of $\text{res}(P)$ which is smaller than (or equal to) $I$. Then $I$ is a normal model of $\text{res}(P)$, so by Lemma 4.3 it is a model of $P$. By construction, it is a model of $\mathcal{D-WFS}(P)$. Furthermore, $I \not\models \text{not } A_i$ for $i = 1, \ldots, n$, since $A_i \in \text{heads}(\text{res}(P))$.

2. Let $Q$ be a disjunction of positive ground literals. Since $Q \not\in \mathcal{D-WFS}(P)$, there is no disjunctive fact $\mathcal{A} \models \text{true}$ in $\text{res}(P)$ with $\mathcal{A} \subseteq Q$. Let $I_0$ be the following interpretation:
   • $I_0 \models \text{not } A$ iff $A \not\in \text{heads}(\text{res}(P))$,
   • $I_0 \models A$ iff $A \in \text{heads}(\text{res}(P)) \setminus Q$.

   Since all negative body literals are false in this interpretation, and query is not subsumed by a disjunctive fact, this interpretation is obviously a model of $\text{res}(P)$. Let $I$ be again a smaller minimal model of $\text{res}(P)$. Since already $I_0 \not\models Q$, of course also $I \not\models Q$. By construction, it is also clear that $I$ is a normal model of $\text{res}(P)$, and thus a model of $P$. Furthermore, it obviously satisfies $\mathcal{D-WFS}(P)$. 

Proof of Theorem 5.1.

1. The alternating fixpoint construction of the well-founded model [58], immediately shows that the well-founded semantics has the property that it looks only at the minimal models and not at the syntax of the rules (each application of the fundamental $\mathcal{S}_r$-operator in Ref. [58] constructs one minimal model for a specific interpretation of the negative literals). So Theorem 4.2 becomes applicable and shows that WFS allows unfolding, elimination of tautologies, and elimination of non-minimal rules (plus weak unfolding by Lemma 2.1).

2. Let us show that the well-founded semantics allows positive reduction. Let $P_1 \rightarrow P_2$ and let not $C$ be the negative literal evaluated to true because $C$ appears in no rule head. Note that for any interpretation $I$ satisfying $I \models \text{not } C$, we have:

$$I \text{ is a minimal model of } P_1 \iff I \text{ is a minimal model of } P_2.$$ 

We prove that any set of negative ground literals $I^-$, such that the minimal model of $P_1$ with this interpretation of the negative literals is consistent, satisfies the following:

$$I^- \text{ is a fixpoint of } A_{P_1} \iff I^- \text{ is a fixpoint of } A_{P_2}.$$
where \( A \) is the alternating fixpoint operator defined in Ref. [58]. Of course, this implies that the least fixpoints agree (the consistency requirement is known to hold for the least fixpoint, i.e. the well-founded model).

So suppose that \( I^- \) is a fixpoint of \( \mathcal{A}_P \). Since \( C \) does not appear in any rule head, already the first iteration of \( \mathcal{A}_P \) makes \( \lnot C \) true, so it is certainly contained in \( I^- \). But for such interpretations of the negative literals, \( P_1 \) and \( P_2 \) have identical minimal models. Therefore, \( \mathcal{S}_{P_1}(I^-) = \mathcal{S}_{P_2}(I^-) \). By the consistency requirement, \( \mathcal{S}_{P_1}(I^-) \) does not contain \( C \), so the minimal models considered in the next application of \( \mathcal{S}_{P_1} \) and \( \mathcal{S}_{P_2} \) are again identical. Thus, \( \mathcal{A}_{P_1}(I^-) = \mathcal{A}_{P_2}(I^-) = I^- \), i.e. \( I^- \) is also a fixpoint of \( \mathcal{A}_{P_2} \).

The opposite direction, "\( I^- \) is a fixpoint of \( \mathcal{A}_{P_2} \) ⇒ \( I^- \) is a fixpoint of \( \mathcal{A}_{P_1} \)" is shown analogously.

3. The proof for negative reduction is very similar. Note that negative reduction is simpler in the non-disjunctive case than in the general case, since it suffices to consider a single negative literal \( \lnot C \). Again, minimal models agree if they only interpret the \( \lnot C \) as false. □

**Proof of the Theorem 5.2.** Since the WFS allows our transformations (Theorem 5.1), we can conclude from Corollary 4.3 that the well-founded model of the residual program is equal to the well-founded model of the original program (for this result see also Ref. [1]). Note that our transformations never introduce new disjunctions, so it is no problem that WFS is only defined on non-disjunctive programs.

Let us write \( D\text{-}\text{WFS}' \) for the set of ground literals contained in \( D\text{-}\text{WFS} \). Because of the special form of the residual program, it is easy to show \( D\text{-}\text{WFS}'(\text{res}(P)) = \text{WFS}(\text{res}(P)) \):

1. The direction \( \subseteq \) is obvious: any fixpoint \( I^- \) of \( \mathcal{A}_{\text{res}(P)} \) must contain all \( \lnot A \), where \( A \not\in \text{heads}(\text{res}(P)) \). Furthermore, \( \mathcal{S}_{\text{res}(P)}(I^-) \) certainly contains all atoms \( A \) which are facts in \( \text{res}(P) \).

2. In order to prove that the well-founded semantics makes all other ground atoms \( A \) undefined, we show that \( I^- := \{ \lnot A | A \not\in \text{heads}(\text{res}(P)) \} \) is already a fixpoint of \( \mathcal{A}_{\text{res}(P)} \) (and then it is certainly the least).

\( \mathcal{S}_{\text{res}(P)}(I^-) \) contains only the atoms, which are given as facts in \( \text{res}(P) \). But then the negations of all other atoms are assumed and this allows us to derive all atoms in \( \text{heads}(\text{res}(P)) \). Taking the complement gives us again \( I^- \).

So we have for all non-disjunctive programs \( P \): \( \text{WFS}(P) = \text{WFS}(\text{res}(P)) = D\text{-}\text{WFS}'(\text{res}(P)) = D\text{-}\text{WFS}'(P) \). □

**Proof of Theorem 5.3.**

1. The stable model semantics looks only at minimal models: it simply selects those among the minimal models which are total and consistent (i.e. "2-valued"). So Theorem 4.2 becomes applicable and shows that STABLE allows unfolding, elimination of tautologies, and elimination of non-minimal rules (plus weak unfolding by Lemma 2.1). We have proven these properties already in Ref. [5]. Unfolding was independently established in Ref. [57].

2. Positive reduction: let \( P_1 \Rightarrow_p P_2 \) and let \( \lnot C \) be the negative literal evaluated to true.
Let I be a stable model of $P_1$. Since $C$ occurs in no rule head, $I \models \neg C$, and thus $I$ is also a model of $P_2$. There can be no smaller model, since every model of $P_2$ is also a model of $P_1$ and $I$ was assumed to be stable and thus minimal.

Conversely, let I be a stable model of $P_2$. It is clear that I is also a model of $P_1$. Furthermore, $I \models \neg C$, so if there were a smaller model $I_0$ of $P_1$, this would also be a model of $P_2$, contradicting again the minimality of $I$.

3. Negative reduction: let $P_1 \leftarrow_{\neg} P_2$ and let $\forall \neg \leftarrow \exists \neg \not \in \text{rule which was}$

deleted because of the fact $\forall' \leftarrow \exists'$ true with $\forall' \not \subseteq \forall$.

Let I be a stable model of $P_1$. Since $P_2 \subseteq P_1$, I is also a model of $P_2$. If there were a smaller model $I_0$ of $P_2$, this would also be a model of $P_1$ since $I \not \models \neg C$ and thus $I_0 \not \models \neg C$. This would contradict the assumed minimality of $I$.

Let I be a stable model of $P_2$. Then $I \not \models \neg C$, thus I is also a model of $P_1$. If there were a smaller model $I_0$, this would also be a model of $P_2$ (since $P_2 \subseteq P_1$), contradicting again the minimality of $I$.

Proof of the Theorem 5.4. Given a positive program $P$, positive and negative Reduction are obviously not needed in the construction of the residual program, so it can be reached by unfolding, weak unfolding, elimination of tautologies and elimination of nonminimal rules. These transformations do not change the set of minimal models and therefore they do not change the negative literals assumed by the GCWA. So it suffices to consider residual programs which in this case are sets of minimal positive disjunctions.

1. Let $\not A \in \text{D-WFS}(P)$. The D-WFS assumes $\not A$ only if $A$ does not appear in $\text{res}(P)$. Then $A$ is of course false in all minimal models, and thus the GCWA assumes $\not A$.

2. Let $\not A \not \in \text{D-WFS}(P)$. Then $A$ appears in a disjunction in $\text{res}(P)$, say $A \vee A_1 \vee \cdots \vee A_n$. Let $I$ be the interpretation which makes $A_1, \ldots, A_n$ false, and all other atoms true. Since $A \vee A_1 \vee \cdots \vee A_n$ is a minimal disjunction, $I$ is a model of $\text{res}(P)$. Now let $I_0$ be a smaller minimal model. Since $A$ must be true in $I_0$, $\not A$ cannot be assumed by the GCWA.
