Complementary Pivot Theory of Mathematical Programming

RICHARD W. COTTLE AND GEORGE B. DANTZIG
Stanford University
Stanford, California

1. FORMULATION

Linear programming, quadratic programming, and bimatrix (two-person, nonzero-sum) games lead to the consideration of the following fundamental problem

\[ w = q + Mz, \quad w \geq 0, \quad z \geq 0, \quad zw = 0. \]

The remainder of this section is devoted to an explanation of why this is so. (There are other fields in which this fundamental problem arises—see, for example, [6] and [13]—but we do not treat them here.) Sections 2 and 3 are concerned with constructive procedures for solving the fundamental problem under various assumptions on the data \( q \) and \( M \).

---

1 The fundamental problem can be extended from \( p \) sets each consisting of a pair of variables only one of which can be nonbasic to \( k \) sets of several variables each, only one of which can be nonbasic. To be specific, consider a system \( w = q + Nz \), \( w \geq 0, \ z \geq 0 \), where \( N \) is a \( p \times k \) matrix (\( k \leq p \)) and the variables \( w_1, \ldots, w_p \) are partitioned into \( k \) nonempty sets \( S_l, \ l = 1, \ldots, k \). Let \( T_l = S_l \cup \{ q \}, \ l = 1, \ldots, k \). We seek a solution of the system in which exactly one member of each set \( T_l \) is nonbasic. (The fundamental problem is of this form where \( k = p \) and \( T_l = \{ w_l, z_l \} \).) The underlying idea of Lemke's approach (Section 2) applies here. For example, it can be shown that this problem has a solution when \( N > 0 \). A paper is currently being prepared for publication in which this extension is developed in detail.

2 In general, capital italic letters denote matrices while vectors are denoted by lower case italic letters. Whether a vector is a row or a column will always be clear from the context, and consequently we dispense with transpose signs on vectors. In (2), for example, \( zw \) represents the scalar product of \( z \) (row) and \( w \) (column). The superscript \( T \) indicates the transpose of the matrix to which it is affixed.

Linear Algebra and Its Applications 1, 103—125 (1968)
Consider first linear programs in the symmetric primal-dual form due to J. von Neumann [20].

**Primal linear program:** Find a vector $x$ and minimum $\bar{z}$ such that

$$Ax \geq b, \quad x \geq 0, \quad \bar{z} = cx. \quad (3)$$

**Dual linear program:** Find a vector $y$ and maximum $z$ such that

$$yA \leq c, \quad y \geq 0, \quad z = yb. \quad (4)$$

The duality theorem of linear programming [3] states that $\min \bar{z} = \max z$ when the primal and dual systems (3) and (4), respectively, are consistent or—in mathematical programming parlance—"feasible." Since

$$\bar{z} = yb \leq yAx \leq cx = \bar{z}$$

for all primal-feasible $x$ and dual-feasible $y$, one seeks such solutions for which

$$yb = cx. \quad (5)$$

The inequality constraints of the primal and dual problems can be converted to equivalent systems of equations in nonnegative variables through the introduction of nonnegative "slack" variables. Jointly, the systems (3) and (4) are equivalent to

$$Ax - v = b, \quad v \geq 0, \quad x \geq 0,$$

$$ATy + u = c, \quad u \geq 0, \quad y \geq 0, \quad (6)$$

and the linear programming problem becomes one of finding vectors $u, v, x, y$ such that

$$\begin{pmatrix} u \\ v \end{pmatrix} - \begin{pmatrix} c \\ -b \end{pmatrix} + \begin{pmatrix} 0 & -AT \\ A & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}, \quad u \geq 0, \quad v \geq 0,$$

$$x \geq 0, \quad y \geq 0, \quad (7)$$

and, by (5),

$$xu + yv = 0. \quad (8)$$

The definitions

$$w = \begin{pmatrix} u \\ v \end{pmatrix}, \quad q = \begin{pmatrix} c \\ -b \end{pmatrix}, \quad M = \begin{pmatrix} 0 & -AT \\ A & 0 \end{pmatrix}, \quad z = \begin{pmatrix} x \\ y \end{pmatrix} \quad (9)$$

establish the correspondence between (1), (2) and (3), (4).

*Linear Algebra and Its Applications* 1, 103–125 (1968)
The quadratic programming problem is typically stated in the following manner: Find a vector $x$ and minimum $\tilde{z}$ such that

$$Ax \geq b, \quad x \geq 0, \quad \tilde{z} = cx + \frac{1}{2}x^TDx. \quad (10)$$

In this formulation, the matrix $D$ may be assumed to be symmetric. The minimand $\tilde{z}$ is a globally convex function of $x$ if and only if the quadratic form $x^TDx$ (or matrix $D$) is positive semidefinite, and when this is the case, (10) is called the convex quadratic programming problem. It is immediate that when $D$ is the zero matrix, (10) reduces to the linear program (3). In this sense, the linear programming problem is a special case of the quadratic programming problem.

For any quadratic programming problem (10), define $u$ and $v$ by

$$u = Dx - A^T y + c, \quad v = Ax - b. \quad (11)$$

A vector $x^0$ yields minimum $\tilde{z}$ only if there exists a vector $y^0$ and vectors $u^0, v^0$ given by (11) for $x = x^0$ satisfying

$$x^0 \geq 0, \quad u^0 \geq 0, \quad y^0 \geq 0, \quad v^0 \geq 0,$$

$$x^0u^0 = 0, \quad y^0v^0 = 0. \quad (12)$$

These necessary conditions for a minimum in (10) are a direct consequence of a theorem of H. W. Kuhn and A. W. Tucker [14]. It is well known—and not difficult to prove from first principles—that (12), known as the Kuhn-Tucker conditions, are also sufficient in the case of convex quadratic programming. By direct substitution, we have for any feasible vector $x$,

$$\tilde{z} - z^0 = c(x - x^0) + \frac{1}{2}x^TDx - \frac{1}{2}x^0Dx^0$$

$$= u^0(x - x^0) + y^0(v - v^0) + \frac{1}{2}(x - x^0)D(x - x^0)$$

$$= u^0x + y^0v + \frac{1}{2}(x - x^0)D(x - x^0) \geq 0,$$

which proves the sufficiency of conditions (12) for a minimum in the convex case.

Thus, the problem of solving a quadratic program leads to a search for solution of the system

$$u = Dx - A^T y + c, \quad x \geq 0, \quad y \geq 0,$$

$$v = Ax - b, \quad u \geq 0, \quad v \geq 0,$$

$$xu + yv = 0. \quad (13)$$
The definitions

\[
\begin{align*}
  w &= \begin{pmatrix} u \\ v \end{pmatrix}, \quad q = \begin{pmatrix} c & -b \\ -b & b \end{pmatrix}, \quad M = \begin{pmatrix} D & -A^T \\ A & E \end{pmatrix}, \quad z = \begin{pmatrix} x \\ y \end{pmatrix}
\end{align*}
\]  

establish (13), (14) as a problem of the form (1), (2).

**Dual of a convex quadratic program.** From (15) one is led naturally to the consideration of a matrix \( M = \begin{pmatrix} D & -A^T \\ A & E \end{pmatrix} \) wherein \( E \), like \( D \), is positive semidefinite. It is shown in [1] that the

**Primal quadratic program:** Find \( x \) and minimum \( \bar{z} \) such that

\[
Ax + Ey \geq b, \quad x \geq 0, \quad \bar{z} = cx + \frac{1}{2}(xDx + yEy),
\]  

has the associated

**Dual quadratic program:** Find \( y \) and maximum \( z \) such that

\[
-Dx + Ay \leq c, \quad y \geq 0, \quad z = by - \frac{1}{2}(xDx - yEy).
\]  

All the results of duality in linear programming extend to these problems, and indeed they are jointly solvable if either is solvable. When \( E = 0 \), the primal problem is just (10), for which W. S. Dorn [5] first established the duality theory later extended in [1]. When both \( D \) and \( E \) are zero matrices, this dual pair (16), (17) reduces to the dual pair of linear programs (3), (4).

**Remarks.** (a) The minimand in (10) is strictly convex if and only if the quadratic form \( xDx \) is positive definite. Any feasible strictly convex quadratic program has a unique minimizing solution \( x^0 \). (b) When \( D \) and \( E \) are positive semidefinite (the case of convex quadratic programming), so is

\[
M = \begin{pmatrix} D & -A^T \\ A & E \end{pmatrix}.
\]

A bimatrix (or two-person nonzero-sum game), \( \Gamma(A, B) \), is given by a pair of \( m \times n \) matrices \( A \) and \( B \). One party, called the row player, has \( m \) pure strategies which are identified with the rows of \( A \). The other party, called the column player, has \( n \) pure strategies which correspond to the columns of \( B \). If the row player uses his \( i \)th pure strategy and the column player uses his \( j \)th pure strategy, then their respective losses are defined as \( a_{ij} \) and \( b_{ij} \), respectively. Using mixed strategies,
their expected losses are $xAy$ and $xB$, respectively. (A component in a mixed strategy is interpreted as the probability with which the player uses the corresponding pure strategy.)

A pair $(x^0, y^0)$ of mixed strategies is a Nash [19] equilibrium point of $\Gamma(A, B)$ if

\begin{align*}
  &x^0Ay^0 \leq A^0y^0, \quad \text{all mixed strategies } x, \\
  &x^0By^0 \leq x^0By, \quad \text{all mixed strategies } y.
\end{align*}

It is evident (see, for example, [15]) that if $(x^0, y^0)$ is an equilibrium point of $\Gamma(A, B)$, then it is also an equilibrium point for the game $\Gamma(A'B')$ in which

\begin{align*}
  &A' = [a_{ij} + K], \quad B' = [b_{ij} + L],
\end{align*}

where $K$ and $L$ are arbitrary scalars. Hence there is no loss of generality in assuming that $A > 0$ and $B > 0$, and we shall make this assumption hereafter.

Next, by letting $e_k$ denote the $k$-vector all of whose components are unity, it is easily shown that $(x^0, y^0)$ is an equilibrium point of $\Gamma(A, B)$ if and only if

\begin{align*}
  & (x^0Ay^0)e_m \leq A^0e_m, \quad (A > 0), \quad (18) \\
  & (x^0By^0)e_n \leq B^0e_n, \quad (B > 0). \quad (19)
\end{align*}

This characterization of an equilibrium point leads to a theorem which relates the equilibrium-point problem to a system of the form (1), (2). For $A > 0$ and $B > 0$, if $u^*, v^*, x^*, y^*$ is a solution of the system

\begin{align*}
  u &= Ay - e_m, \quad u \geq 0, \quad y \geq 0, \\
  v &= B^Tx - e_n, \quad v \geq 0, \quad x \geq 0,
\end{align*}

then

\begin{align*}
  (x^0, y^0) = \left( \frac{x^*}{x^*e_m}, \frac{y^*}{y^*e_n} \right)
\end{align*}

*Linear Algebra and Its Applications* 1, 103–125 (1968)
is an equilibrium point of $\Gamma(A, B)$. Conversely, if $(x^0, y^0)$ is an equilibrium point of $\Gamma(A, B)$ then

$$ (x^*, y^*) = \left( \begin{array}{c} x^0 \\ y^0 \\ y^0 \\ x^0A y^0 \end{array} \right) $$

is a solution of (20), (21). The latter system is clearly of the form (1), (2), where

$$ w = \begin{pmatrix} u \\ v \end{pmatrix}, \quad q = \begin{pmatrix} -e_m \\ -e_n \end{pmatrix}, \quad M = \begin{pmatrix} 0 & A \\ B^T & 0 \end{pmatrix}, \quad z = \begin{pmatrix} x \\ y \end{pmatrix}. $$

Notice that the assumption $A > 0$, $B > 0$ precludes the possibility of the matrix $M$ above belonging to the positive semidefinite class.

The existence of an equilibrium point for $\Gamma(A, B)$ was established by J. Nash [10] whose proof employs the Brouwer fixed-point theorem. Recently, an elementary constructive proof was discovered by C. E. Lemke and J. T. Howson, Jr. [15].

2. LEMKE'S ITERATIVE SOLUTION OF THE FUNDAMENTAL PROBLEM

This section is concerned with the iterative technique of Lemke and Howson for finding equilibrium points of bimatrix games which was later extended by Lemke to the fundamental problem (1), (2). We introduce first some terminology common to the subject of this section and the next. Consider the system of linear equations

$$ w = q + Mz, \quad (22) $$

where, for the moment, the $p$-vector $q$ and the $p \times p$ matrix $M$ are arbitrary. Both $w$ and $z$ are $p$-vectors.

For $i = 1, \ldots, p$ the corresponding variables $z_i$ and $w_i$ are called complementary and each is the complement of the other. A complementary solution of (22) is a pair of vectors satisfying (22) and

$$ z_i w_i = 0, \quad i = 1, \ldots, p. \quad (23) $$

Notice that a solution $(w; z)$ of (1), (2) is a nonnegative complementary solution of (22). Finally, a solution of (22) will be called almost complementary if it satisfies (23) except for one value of $i$, say $i = \beta$. That is, $z_\beta \neq 0$, $w_\beta \neq 0$.

In general, the procedure assumes as given an extreme point of the convex set

*Linear Algebra and Its Applications* 1. 103–125 (1968)
which also happens to be the end point of an almost complementary ray (unbounded edge) of $Z$. Each point of this ray satisfies (23) but for one value of $i$, say $\beta$. It is not always easy to find such a starting point for an arbitrary $M$. Yet there are two important realizations of the fundamental problem which can be so initiated. The first is the bimatrix game case to be discussed soon; the second is the case where an entire column of $M$ is positive. The latter property can always be artificially induced by augmenting $M$ with an additional positive column; as we shall see, this turns out to be a useful device for initiating the procedure with a general $M$.

Each iteration corresponds to motion from an extreme point $P_i$ along an edge of $Z$ all points of which are almost complementary solutions of (22). If this edge is bounded, an adjacent extreme point $P_{i+1}$ is reached which is either complementary or almost complementary. The process terminates if (i) the edge is unbounded (a ray), (ii) $P_{i+1}$ is a previously generated extreme point, or (iii) $P_{i+1}$ is a complementary extreme point.

Under the assumption of nondegeneracy, the extreme points of $Z$ are in one-to-one correspondence with the basic feasible solutions of (22) (see [3]). Still under this assumption, a complementary basic feasible solution is one in which the complement of each basic variable is nonbasic. The goal is to obtain a basic feasible solution with such a property. In an almost complementary basic feasible of (23), there will be exactly one index, say $\beta$, such that both $w_\beta$ and $z_\beta$ are basic variables. Likewise, there will be exactly one index, say $r$, such that both $w_r$ and $z_r$ are nonbasic variables.\textsuperscript{3}

An almost complementary edge is generated by holding all nonbasic variables at value zero and increasing either $z_r$ or $w_r$ of the nonbasic pair $z_r, w_r$. There are consequently exactly two almost complementary edges associated with an almost complementary extreme point (corresponding to an almost complementary basic feasible solution).

Suppose that $z_r$ is the nonbasic variable to be increased. The values of the basic variables will change linearly with the changes in $z_r$. For sufficiently small positive values of $z_r$, the almost complementary solution remains feasible. This is a consequence of the nondegeneracy assumption.

\textsuperscript{3} C. van de Panne and A. Whinston [21] have used the appropriate terms basic and nonbasic pair for $\{w_\beta, z_\beta\}$ and $\{w_r, z_r\}$ respectively.
But in order to retain feasibility, the values of the basic variables must be prevented from becoming negative.

If the value of \( z_v \) can be made arbitrarily large without forcing any basic variable to become negative, then a ray is generated. In this event, the process terminates. However, if some basic variable blocks the increase of \( z_v \) (i.e., vanishes for a positive value of \( z_v \)), then a new basic solution is obtained which is either complementary or almost complementary. A complementary solution occurs only if a member of the basic pair blocks \( z_v \). A new almost complementary extreme point solution is obtained if the blocking occurs otherwise. In the complementary case, we have the desired result: a complementary basic feasible solution. In the almost complementary case, the nondegeneracy assumption guarantees the uniqueness of the blocking variable. It will become nonbasic in place of \( z_v \) and its index becomes the new value of \( v \).

The complementary rule

The complement of the (now nonbasic) blocking variable—or equivalently put, the other member of the "new" nonbasic pair—is the next nonbasic variable to be increased. The procedure consists of the iteration of these steps. The generated sequence of almost complementary extreme points and edges is called an almost complementary path.

**Theorem 1.** Along an almost complementary path, the only almost complementary basic feasible solution which can reoccur is the initial one.

**Proof.** We assume that all basic feasible solutions of (22) are nondegenerate. (This can be assured by any of the standard lexicographic techniques [3] for resolving the ambiguities of degeneracy.) Suppose, contrary to the assertion of the theorem, that the procedure generates a sequence of almost complementary basic feasible solutions in which a term other than the first one \( (P_0 \) in the accompanying figure) is repeated.
(say \( P_1 \)). By the nondegeneracy assumption, the extreme points of \( Z \) are in one-to-one correspondence with basic feasible solutions of (22). Let \( P_2 \) denote the successor of \( P_1 \) and let \( P_k \) denote the second predecessor to \( P_1 \), namely the one along the path just before the return to \( P_1 \). The extreme points \( P_0, P_2, P_k \) are distinct and each is adjacent to \( P_1 \) along an almost complementary edge. But there are only two such edges at \( P_1 \). This contradiction completes the proof.

We can immediately state the

**Corollary.** *If the almost complementary path is initiated at the end point of an almost complementary ray, the procedure must terminate either in a different ray or in a complementary basic feasible solution.*

It is easy to show by examples that starting from an almost complementary basic feasible solution which is not the end point of an almost complementary ray, the procedure can return to the initial point regardless of the existence or nonexistence of a solution to (1), (2).

**Example 1.** The set \( Z \) associated with

\[
q = \begin{pmatrix} 1 \\ -1 \\ 3 \end{pmatrix}, \quad M = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ -1 & -1 & -1 \end{pmatrix}
\]

is nonempty and bounded. It is clear that no solution of (1) can also satisfy (2) since \( z_1 w_1 > 0 \). Let the extreme point corresponding to the solution \( w = (1, 0, 0), z = (1, 0, 2) \) be the initial point of a path which begins by increasing \( z_2 \). This will return to the initial extreme point after 4 iterations.

**Example 2.** The set \( Z \) associated with

\[
q = \begin{pmatrix} 1 \\ -1 \\ 3 \\ 1 \end{pmatrix}, \quad M = \begin{pmatrix} 0 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ -1 & -1 & -1 & -1 \\ 0 & 0 & 0 & -1 \end{pmatrix}
\]

is likewise nonempty and bounded. The corresponding fundamental problem (1), (2) has a complementary solution \( w = (1, 0, 1, 0), z = (0, 1, 0, 1) \). Yet by starting at \( w = (1, 2, 0, 1), z = (3, 0, 0, 0) \) and in-
creasing $z_3$, the method generates a path which returns to its starting point after 4 iterations.

Furthermore, even if the procedure is initiated from an extreme point at the end of an almost complementary ray, termination in a ray is possible whether or not the fundamental problem has a solution.

**Example 3.** Given the data

$$q = \begin{pmatrix} 1 \\ -1 \\ 3 \\ 1 \end{pmatrix}, \quad M = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & -1 & -1 & 1 \\ 0 & 0 & 0 & -1 \end{pmatrix},$$

the point of $Z$ which corresponds to $w = (1, 0, 4, 1), z = (1, 0, 0, 0)$ is at the end of an almost complementary ray, $w = (1, w_2, 4 + w_2, 1), z = (1 + w_2, 0, 0, 0)$. Moving along the edge generated by increasing $z_2$ leads to a new almost complementary extreme point at which the required increase of $z_3$ is unblocked, so that the process terminates in a ray, and yet the fundamental problem is solved by

$$w = (2, 0, 1, 0), \quad z = (0, 1, 0, 1).$$

**Example 4.** In the problem with

$$q = \begin{pmatrix} 1 \\ -1 \end{pmatrix}, \quad M = \begin{pmatrix} 0 & 0 \\ 1 & -1 \end{pmatrix},$$

the inequalities (1) have solutions, but none of them satisfies (2). The point corresponding to $(w; z) = (1, 0; 1, 0)$ is at the end of an almost complementary ray $w = (1, w_2), z = (w_2, 0)$. When $z_2$ is increased, it is not blocked, and the process terminates in a ray.

**Consequences of termination in a ray**

In this geometrical approach to the fundamental problem, it is useful to interpret algebraically the meaning of termination in an almost complementary ray. This can be achieved by use of a standard result in linear inequality theory [11, 3].

**Lemma.** If $(w^*; z^*)$ is an almost complementary basic feasible solution of (22), and $(w^*; z^*)$ is incident to an almost complementary ray, there exist $p$-vectors $w^h, z^h$ such that

$$w^h = Mz^h, \quad w^h \geq 0, \quad z^h \geq 0, \quad z^h \neq 0$$

Linear Algebra and Its Applications 1, 103–125 (1968)
and points along the almost complementary ray are of the form

\[(w^* + \lambda w^h, z^* + \lambda z^h), \quad \lambda \geq 0,\]  

and satisfy

\[(w_i^* + \lambda w_i^h)(z^* + \lambda z_i^h) = 0 \quad \text{for all } \lambda \geq 0, \text{ and all } i \neq \beta.\]  

**Theorem 2.** If \(M > 0\), (22) has a complementary basic feasible solution for any vector \(q\).

**Proof.** Select \(w_1, \ldots, w_p\) as the basic variables in (22). We may assume that \(q \geq 0\) for otherwise \((w; z) = (q; 0)\) immediately solves the problem. A starting ray of feasible almost complementary solutions is generated by taking a sufficiently large value of any nonbasic variable, say \(z_1\). Reduce \(z_1\) toward zero until it reaches a value \(z_1^* \geq 0\) at which a unique basic variable (assuming nondegeneracy) becomes zero. An extreme point has then been reached.

The procedure has been initiated in the manner described by the corollary above, and consequently the procedure must terminate either in a complementary basic feasible solution or in an almost complementary ray after some basic feasible solution \((w^*; z^*)\) is reached. We now show that the latter cannot happen. For if it does, conditions (24)-(26) of the lemma obtain with \(\beta = 1\). Since \(M > 0\) and \(z^h \geq 0\), this implies \(w^h > 0\). Hence by (26), \(z_i^* = z_i^h = 0\) for all \(i \neq 1\). Hence the only variables which change with \(\lambda\) are \(z_1\) and the components of \(w\). Therefore the final generated ray is the same as the initiating ray, which contradicts the corollary.

**Theorem 3.** A bimatrix game \(\Gamma(A, B)\) has an extreme equilibrium point.

**Proof.** Initiate the algorithm by choosing the smallest positive value of \(x_1\), say \(x_1^0\), such that

\[v = -e_n + B_1^T x_1^0 \geq 0,\]  

where \(B_1^T\) is the first column of \(B^T\). With

\[v^0 = -e_n + B_1^T x_1^0\]
it follows (assuming nondegeneracy) that $v^0$ has exactly one zero component, say the $r$th. The ray is generated by choosing as basic variables $x_i$ and all the slack variables $u, v$ except for $v_r$. The complement of $v_r$, namely $y_r$, is chosen as the nonbasic variable to increase indefinitely. For sufficiently large values of $y_r$, the basic variables are all nonnegative and the ray so generated is complementary except possibly $x_1 u_1$ might not equal 0. Letting $y_r$ decrease toward zero, the initial extreme point is obtained for some positive value of $y_r$.

If the procedure does not terminate in an equilibrium point, then by the corollary, it terminates in an almost complementary ray. The latter implies the existence of a class of almost complementary solutions of the form

$$
\begin{align*}
(u^*, v^*) &= ( -e_m^* + \lambda x^h, v^*_r + \lambda v^h), \\
(y^*, z^*) &= (y^*_r + \lambda y^h).
\end{align*}
$$

Assume first that $x^h \neq 0$. Then $v^h = B^T x^h > 0$. By (30), $y^*_j + \lambda y^h_j = 0$ for all $j$ and all $\lambda \geq 0$. But then $u^* + \lambda u^h = -e_m < 0$, a contradiction.

Assume next that $y^h \neq 0$ and $x^h = 0$. Then $v^h = Ay^h > 0$. By (29), $x^*_i = 0$ for all $i \neq 1$; and $x^*_i = 0$ for all $i$. Hence $v^h = B^T x^h = 0$ and $v^*$ is the same as $v$ defined by (27) since $x_1$ must be at the smallest value in order that $(u^*, v^*, x^*, y^*)$ be an extreme-point solution. By the nondegeneracy assumption, only $v^*_r = 0$, and $v^*_j > 0$ for all $j \neq r$. Hence (30) implies $y^*_j + \lambda y^h_j = 0$ for all $j \neq r$. It is now clear that the postulated terminating ray is the original ray. This furnishes the desired contradiction. The algorithm must terminate in an equilibrium point of the bimatrix game $T(A, B)$.

A modification of almost complementary basic sets

Consider the system of equations

$$
\begin{align*}
w &= q + e_p z_0 + M z,
\end{align*}
$$

where $z_0$ represents an "artificial variable" and $e_p$ is a $p$-vector $(1, \ldots, 1)$. It is clear that (31) always has nonnegative solutions. A solution of (31) is called almost complementary if $z_i w_i = 0$ for $i = 1, \ldots, p$ and is complement.

---

4 The notational analogy with the previously studied case $M > 0$ is obvious.
elementary if, in addition, \( z_0 = 0 \). (See [16, p. 685] where a different but equivalent definition is given.) In this case, let

\[
Z_0 = \{(z_0, z) \mid w = q + e_p z_0 + M z \geq 0, \quad z_0 \geq 0, \quad z \geq 0\}.
\]

We consider the almost complementary ray generated by sufficiently large \( z_0 \). The variables \( w_1, \ldots, w_p \) are initially basic while \( z_0, z_1, \ldots, z_p \) are nonbasic variables. For a sufficiently large value of \( z_0 \), say \( z_0^+ \),

\[
w^+ = q + e_p z_0^+ > 0.
\]

As \( z_0 \) decreases toward zero, the basic variables \( w_i \) decrease. An initial extreme point is reached when \( z_0 \) attains the minimum value \( z_0^0 \) for which \( w = q + e_p z_0 \geq 0 \). If \( z_0^0 = 0 \), then \( q \geq 0 \); this is the trivial case for which no algorithm is required. If \( z_0^0 > 0 \), some unique basic variable, say \( w_r \), has reached its lower bound 0. Then \( z_0 \) becomes a basic variable in place of \( w_r \) and we have \( v = r \). Next, \( z_r \), the complement of \( w_r \), is to be increased.

The remaining steps of the procedure are now identical to those in the preceding algorithm. After a blocking variable becomes basic, its complement is increased until either a basic variable blocks the increase (by attaining its lower bound 0) or else an almost complementary ray is generated. There are precisely two forms of termination. One is in a ray as just described; the other is in the reduction of \( z_0 \) to the value 0 and hence the attainment of a complementary basic feasible solution of (31), i.e., a solution of (1), (2).

Interest now centers on the meaning of termination in an almost complementary ray solution of (31). For certain classes of matrices, the process described above terminates in an almost complementary ray if and only if the original system (1) has no solution. In the remainder of this section, we shall amplify the preceding statement.

If termination in an almost complementary ray occurs after the process reaches a basic feasible solution \((w^*; z_0^*, z^*)\) corresponding to an extreme point of \( Z_0 \), then there exists a nonzero vector \((w^k; z_0^k, z^k)\) such that

\[
w^k = e_p z_0^k + M z^k, \quad (w^k; z_0^k, z^k) \geq 0.
\]

Moreover for every \( \lambda \geq 0 \),

\[
(w^* + \lambda w^k) = q + e_p(z_0^* + \lambda z_0^k) + M(z^* + \lambda z^k)
\]

Linear Algebra and Its Applications 1, 103 125 (1968)
and
\[(w_i^* + \lambda z_i^h)(z_i^* + \lambda z_i^h) = 0, \quad i = 1, \ldots, p.\] (34)

The case \(z^h = 0\) is ruled out, for otherwise \(z_0^h > 0\) and then \(w^h > 0\) because \((w_i^h, z_i^h, z_i^h) \neq 0\). Now if \(w^h > 0\), (34) implies \(z_i^* + \lambda z_i^h = z_i^* = 0\). This, in turn, implies that the ray is the original one, which is not possible.

Furthermore, it follows from the almost complementarity of solutions along the ray that
\[z_i^* w_i^* = z_i^* w_i^h = z_i^h w_i^* = z_i^h w_i^h = 0, \quad i = 1, \ldots, p.\] (35)

The individual equations of the system (32) are of the form
\[w_i^h = z_i^h + (Mz_i^h), \quad i = 1, \ldots, p.\] (36)

Multiplication of (36) by \(z_i^h\) leads, via (35), to
\[0 = z_i^h z_i^h z_i^h + z_i^h (Mz_i^h), \quad i = 1, \ldots, p.\] (37)

from which we conclude that

**Theorem 4.** Termination in a ray implies there exists a nonzero nonnegative vector \(z_i^h\) such that
\[z_i^h(Mz_i^h) \leq 0, \quad i = 1, \ldots, p.\] (38)

At this juncture, two large classes of matrices \(M\) will be considered. For the first class, we show that termination in a ray implies the inconsistency of the system (1). For the second class, we will show that termination in a ray cannot occur, so that for this class of matrices, (1), (2) always has a solution regardless of what \(q\) is.

The first class mentioned above was introduced by Lemke [15]. These matrices, which we shall refer to as copositive plus, are required to satisfy the two conditions
\[uM^u \geq 0 \quad \text{for all} \quad u \geq 0, \quad (M + M^T)u = 0 \quad \text{if} \quad uM^u = 0 \quad \text{and} \quad u \geq 0.\] (39) (40)

Matrices satisfying conditions (39) alone are known in the literature as copositive (see [18, 12]). To our knowledge, there is no reference other than [16] on copositive matrices satisfying the condition (40). However, the class of such matrices is large and includes

*Linear Algebra and Its Applications* 1, 103–125 (1968)
(i) all strictly copositive matrices, i.e., those for which $uM u > 0$ when $0 \neq u \geq 0$;

(ii) all positive semidefinite matrices, i.e., those for which $uM u \geq 0$ for all $u$.

Positive matrices are obviously strictly copositive while positive definite matrices are both positive semidefinite and strictly copositive. Furthermore, it is possible to "build" matrices satisfying (39) and (40) out of smaller ones. For example, if $M_1$ and $M_2$ are matrices satisfying (39) and (40) then so is the block-diagonal matrix

$$M = \begin{pmatrix} M_1 & 0 \\ 0 & M_2 \end{pmatrix}.$$ 

Moreover, if $M$ satisfies (39) and (40) and $S$ is any skew-symmetric matrix (of its order), then $M + S$ satisfies (39) and (40). Consequently, block matrices such as

$$M = \begin{pmatrix} M_1 & -A^T \\ A & M_2 \end{pmatrix}$$

satisfy (39) and (40) if and only if $M_1$ and $M_2$ do too. However, as Lemke \[16, 17\] has pointed out, the matrices encountered in the bimatrix game problem with $A > 0$ and $B > 0$ need not satisfy (40). The Lemke-Howson iterative procedure for bimatrix games was given earlier in this section. If applied to bimatrix games, the modification just given always terminates in a ray after just one iteration, as can be verified by taking any example.

The second class, consisting of matrices having positive principal minors, has been studied by numerous investigators; see, for example, [2, 4, 8, 9, 10, 22, 24]. In the case of symmetric matrices, those with positive principal minors are positive definite. But the equivalence breaks down in the nonsymmetric situation. Nonsymmetric matrices with positive principal minors need not be positive definite. For example, the matrix

$$\begin{pmatrix} 2 & -7 \\ -1 & 4 \end{pmatrix}$$

has positive principal minors but is indefinite and not copositive. However, positive definite matrices are a subset of those with positive principal minors. (See, e.g., [2].)
We shall make use of the fact that \( w = q + Mz, \) \((w; z) \geq 0,\) has no solution if there exists a vector \( v \) such that
\[
vM \leq 0, \quad vq < 0, \quad v \geq 0
\]
for otherwise \( 0 \leq vw = vq + vMz < 0, \) a contradiction. Indeed, it is a consequence of J. Farkas’ theorem [7] that (1) has no solution if and only if there exists a solution of (41).

**Theorem 5.** Let \( M \) be copositive plus. If the iterative procedure terminates in a ray, then (1) has no solution.

**Proof.** Termination in a ray means that a basic feasible solution \((w^*, z_0^*, z^*)\) will be reached at which conditions (32)–(34) hold and also
\[
0 = z^h w^h = z^h e_p z_0^h + z^h M z^h.
\]
(42)
Since \( M \) is copositive and \( z^h \geq 0, \) both terms on the right side of (42) are nonnegative, hence both are zero. The scalar \( z_0^h = 0 \) because \( z^h e_p > 0. \) The vanishing of the quadratic form \( z^h M z^h \) means
\[
M z^h + M^T z^h = 0.
\]
But by (32), \( z_0^h = 0 \) implies that \( w^h = M z^h \geq 0, \) whence \( M^T z^h \leq 0 \) or, what is the same thing, \( z^h M \leq 0. \) Next, by (35),
\[
0 = z^* w^h = z^* M z^h = z^*(- M^T z^h) = - z^h M z^*
\]
and we obtain again by (35)
\[
0 = z^h w^* = z^h q + z^h e_p z_0^* + z^h M z^* = z^h q + z^h e_p z_0^*.
\]
It follows that \( z^h q < 0 \) because \( z^h e_p z_0^* > 0. \) The conditions (I) are therefore inconsistent because \( v = z^h \) satisfies (41).

**Corollary.** If \( M \) is strictly copositive, the process terminates in a complementary basic feasible solution of (31).

**Proof.** If not, the proof of Theorem 5 would imply the existence of a vector \( z^h \) satisfying \( z^* M z^h = 0, \) \( 0 \neq z^h \geq 0, \) which contradicts the strict copositivity of \( M. \)

This corollary clearly generalizes Theorem 1. We now turn to the matrices \( M \) having positive principal minors.

*Linear Algebra and Its Applications* 1, 103–125 (1968)
Theorem 6. If $M$ has positive principal minors, the process terminates in a complementary basic solution of (31) for any $q$.

Proof. We have seen that termination in a ray implies the existence of a nonzero vector $z^h$ satisfying the inequalities (38). However, Gale and Nikaido [10, Theorem 2] have shown that matrices with positive principal minors are characterized by the impossibility of this event. Hence termination in a ray is not a possible outcome for problems in which $M$ has positive principal minors.

We can even improve upon this.

Theorem 7. If $M$ has the property that for each of its principal submatrices $M_i$, the system

$$M_i z = 0, \quad 0 \neq z = 0,$$

has no solution, then the process terminates in a complementary basic solution of (31) for any $q$.

Proof. Suppose the process terminates in a ray. From the solution $(w^h; z_0^h, z^h)$ of the homogeneous system (32), define the vector $\tilde{w}^h$ of components of $w^h$ for which the corresponding component of $z^* + z^h$ is positive. Then by (34) $\tilde{w}^h = 0$. Let $\tilde{z}^h$ be the vector of corresponding components in $z^h$. Clearly $0 \neq \tilde{z}^h \geq 0$, since $0 \neq z^h \geq 0$ and any positive component of $z^h$ is a positive component of $\tilde{z}^h$ by definition of $\tilde{w}^h$. Let $M_i$ be the corresponding principal submatrix of $M$. Since $M_i$ is a matrix of order $k \geq 1$ we may write

$$0 = \tilde{w}^h = c_k z_0^h + M_i \tilde{z}^h.$$

Hence

$$M_i \tilde{z}^h \leq 0, \quad 0 \neq \tilde{z}^h \geq 0,$$

which is a contradiction.

3. THE PRINCIPAL PIVOTING METHOD

We shall now describe an algorithm proposed by the authors [4] which predates that of Lemke. It evolved from a quadratic programming algorithm of P. Wolfe [26], who was the first to use a type of complemen-
tary rule for pivot choice. Our method is applicable to matrices $M$ that have positive principal minors (in particular to positive definite matrices) and, after a minor modification, to positive semidefinite matrices.

In Lemke's procedure for general $M$, an artificial variable $z_0$ is introduced in order to obtain feasible almost complementary solutions for the augmented problem. In our approach, only variables of the original problem are used, but these can take on initially negative as well as non-negative values.

A major cycle of the algorithm is initiated with the complementary basic solution $(w; z) = (q; 0)$. If $q \geq 0$, the procedure is immediately terminated. If $q < 0$, we may assume (relabeling if necessary) that $w_1 = q_1 < 0$. An almost complementary path is generated by increasing $z_i$, the complement of the selected negative basic variable. For points along the path, $z_i w_i = 0$ for $i \neq 1$.

**Step I:** Increase $z_1$ until it is blocked by a positive basic variable decreasing to zero or by the negative $w_1$ increasing to zero.

**Step II:** Make the blocking variable nonbasic by pivoting its complement into the basic set. The major cycle is terminated if $w_1$ drops out of the basic set of variables. Otherwise, return to Step I.

It will be shown that during a major cycle $w_1$ increases to zero. At this point, a new complementary basic solution is obtained. However, the number of basic variables with negative values is at least one less than at the beginning of the major cycle. Since there are at most $p$ negative basic variables, no more than $p$ major cycles are required to obtain a complementary feasible solution of (22). The proof depends on certain properties of matrices invariant under principal pivoting.

**Principal pivot transform of a matrix**

Consider the homogeneous system $v = Mu$ where $M$ is a square matrix. Here the variables $v_1, \ldots, v_p$ are basic and expressed in terms of the nonbasic variables $u_1, \ldots, u_p$. Let any subset of the $v_i$ be made nonbasic and the corresponding $u_i$ basic. Relabel the full set of basic variables $\bar{v}$ and the corresponding nonbasic variables $\bar{u}$. Let $\bar{v} = \bar{M} \bar{u}$ express the new basic variables $\bar{v}$ in terms of the nonbasic ones. The matrix $\bar{M}$ is called a principal pivot transform of $M$. Of course, this transformation can be carried out only if the principal submatrix of $M$ corresponding to the set of variables $z_i$ and $w_i$ interchanged is nonsingular, and this will be assumed whenever the term is used.

*Linear Algebra and Its Applications* 1, 103–125 (1968)
Theorem 8 (Tucker [24]). If a square matrix $M$ has positive principal minors, so does every principal pivot transform of $M$.

The proof of this theorem is easily obtained inductively by exchanging the roles of one complementary pair and evaluating the resulting principal minors in terms of those of $M$.

Theorem 9. If a matrix $M$ is positive definite or positive semidefinite so is every principal pivot transform of $M$.

Proof. The original proof given by the authors was along the lines of that for the preceding theorem. P. Wolfe has suggested the following elegant proof. Consider $v = Mu$. After the principal pivot transformation, let $\tilde{v} = M\tilde{u}$, where $\tilde{u}$ is the new set of nonbasic variables. We wish to show that $\tilde{u}M\tilde{u} = \tilde{u}\tilde{v} > 0$ if $uMu = uv > 0$. If $M$ is positive definite, the latter is true if $u \neq 0$, and the former must hold because every pair $(\tilde{u}, \tilde{v})$ is identical with $(u, v)$ except possibly in reverse order. Hence $\sum_i \tilde{u}_i\tilde{v}_i = \sum_i u_iv_i > 0$. The proof in the semidefinite case replaces the inequality $>$ by $\geq$.

Validity of the algorithm

The proof given below for $p = 3$ goes through for general $p$. Consider

\begin{align*}
  w_1 &= q_1 + m_{11}z_1 + m_{12}z_2 + m_{13}z_3 \\
  w_2 &= q_2 + m_{21}z_1 + m_{22}z_2 + m_{23}z_3 \\
  w_3 &= q_3 + m_{31}z_1 + m_{32}z_2 + m_{33}z_3.
\end{align*}

Suppose that $M$ has positive principal minors so that the diagonal coefficients are all positive:

\begin{align*}
  m_{11} > 0, \quad m_{22} > 0, \quad m_{33} > 0.
\end{align*}

Suppose furthermore that some $q_i$ is negative, say $q_1 < 0$. Then the solution $(w; z) = (q_1, q_2, q_3; 0, 0, 0)$ is complementary, but not feasible because a particular variable, in this case $w_1$, which we refer to as distinguished is negative. We now initiate an almost complementary path by increasing the complement of the distinguished variable, in this case $z_1$, which we call the driving variable. Adjusting the basic variables, we have

\begin{align*}
  (w; z)^1 = (q_1 + m_{11}z_1, q_2 + m_{21}z_1, q_3 + m_{31}z_1; 0, 0, 0).
\end{align*}
Note that the distinguished variable \( w_1 \) increases strictly with the increase of the driving variable \( z_1 \) because \( m_{11} > 0 \). Assuming nondegeneracy, we can increase \( z_1 \) by a positive amount before it is blocked either by \( w_1 \) reaching zero or by a basic variable that was positive and is now turning negative.

In the former case, for some positive value \( z_1^* \) of the driving variable \( z_1 \), we have \( w_1 = q_1 + m_{11}z_1^* = 0 \). The solution

\[
(w; z)^2 = (0, q_2 + m_{21}z_1^*, q_3 + m_{31}z_1^*; 0, 0, 0)
\]
is complementary and has one less negative component. Pivoting on \( m_{11} \) replaces \( w_1 \) by \( z_1 \) as a basic variable. By Theorem 8, the matrix \( \tilde{M} \) in the new canonical system relabeled \( \tilde{w} = \tilde{q} + \tilde{M}z \) has positive principal minors, allowing the entire major cycle to be repeated.

In the latter case, we have some other basic variable, say \( w_2 = q_2 + m_{21}z_1 \) blocking when \( z_1 = z_1^* > 0 \). Then clearly \( m_{21} < 0 \) and \( q_2 > 0 \).

\[
(w; z)^2 = (m_{11}z_1^* + q_1, 0, m_{31}z_1^* + q_3; z_1^*, 0, 0).
\]

**Theorem 10.** If the driving variable is blocked by a basic variable other than its complement, a principal pivot exchanging the blocking variable with its complement will permit the further increase of the driving variable.

**Proof.** Pivoting on \( m_{22} \) generates the canonical system

\[
\begin{align*}
w_1 &= \tilde{q}_1 + \tilde{m}_{11}z_1 + \tilde{m}_{12}w_2 + \tilde{m}_{13}w_3 \\
z_2 &= \tilde{q}_2 + \tilde{m}_{21}z_1 + \tilde{m}_{22}w_2 + \tilde{m}_{23}w_3 \\
w_3 &= \tilde{q}_3 + \tilde{m}_{31}z_1 + \tilde{m}_{32}w_2 + \tilde{m}_{33}w_3.
\end{align*}
\]
The solution \((w; z)^2\) must satisfy the above since it is an equivalent system. Therefore setting \( z_1 = z_1^* \), \( w_2 = 0 \), \( z_3 = 0 \) yields

\[
(w; z)^2 = (q_1 + \tilde{m}_{11}z_1^*, 0, q_3 + \tilde{m}_{31}z_1^*; z_1^*, 0, 0),
\]
i.e., the same almost complementary solution. Increasing \( z_1 \) beyond \( z_1^* \) yields

\[
(\tilde{q}_1 + \tilde{m}_{11}z_1, 0, \tilde{q}_3 + \tilde{m}_{31}z_1; z_1, 0, 0),
\]
which is also almost complementary. The sign of \( \tilde{m}_{21} \) is the reverse of \( m_{21} \), since \( \tilde{m}_{21} = -m_{21}/m_{22} > 0 \). Hence \( z_2 \) increases with increasing \( z_1 > z_1^* \).

*Linear Algebra and Its Applications* 1, 103-125 (1968)
i.e., the new basic variable replacing \( w_2 \) is not blocking. Since \( \bar{M} \) has positive principal minors, \( \bar{m}_{11} > 0 \). Hence \( w_1 \) continues to increase with increasing \( z_1 > z_1^* \).

**Theorem 11.** The number of iterations within a major cycle is finite.

**Proof.** There are only finitely many possible bases. No basis can be repeated with a larger value of \( z_1 \). To see this, suppose it did for \( z_1^{**} > z_1^* \). This would imply that some component of the solution turns negative at \( z_1 = z_1^* \) and yet is nonnegative when \( z_1 = z_1^{**} \). Since the value of a component is linear in \( z_1 \), we have a contradiction.

*Paraphrase of the principal pivoting method*

Along the almost complementary path there is only one degree of freedom. In the proof of the validity of the algorithm, \( z_1 \) was increasing and \( z_2 \) was shown to increase. The same class of solutions can be generated by regarding \( z_2 \) as the driving variable and the other variables as adjusting. Hence within each major cycle, the same almost complementary path can be generated as follows. The first edge is obtained by using the complement of the distinguished variable as the driving variable. As soon as the driving variable is blocked, the following steps are iterated:

(a) replace the blocking variable by the driving variable and terminate the major cycle if the blocking variable is distinguished; if the blocking variable is not distinguished

(b) let the complement of the blocking variable be the new driving variable and increase it until a new blocking variable is identified; return to (a).

The paraphrase form is used in practice.

**Theorem 12.** The principal pivoting method terminates in a solution of (1), (2) if \( M \) has positive principal minors (and, in particular, if \( M \) is positive definite).

**Proof.** We have shown that the completion of a major cycle occurs in a finite number of steps, and each one reduces the total number of variables with negative values. Hence in a finite number of steps, this total is reduced to zero and a solution of the fundamental problem (1), (2)
is obtained. Since a positive definite matrix has positive principal minors, the method applies to such matrices.

As indicated earlier, the positive semidefinite case can be handled by using the paraphrase form of the algorithm with a minor modification. The reader will find details in [4].
