Summary

Contagious ovine digital dermatitis (CODD) is a cause of severe lameness in sheep and the three Treponema phylogroups Treponema medium/Treponema vincentii-like, Treponema phagedenis-like and Treponema pedis have been associated with clinical disease. The aims of this study were: (1) to describe the histopathological changes associated with each previously established grade of clinical lesion, and (2) to investigate immunohistochemically the association of the Treponema-like organisms with the observed histopathological changes. Early lesions were characterized by lymphoplasmacytic infiltration of the distal digital skin, with suppurative coronitis and intracorneal pustules. In more advanced stages of the disease there was complete separation of the dorsal wall of the hoof with a necrotizing and fibrinosuppurative exudate and dermatitis. The later lesions were mostly resolved, but with milder suppurative changes remaining within the cornified layer and periosteal reaction of the dorsal aspect of the distal phalanx. Large numbers of Treponema-like organisms were identified within early grade lesions (as well as later, more advanced grade lesions) and were specifically associated with the observed histopathological changes. The results of this study provide some evidence in support of the hypothesis that the three CODD-associated Treponema phylogroups are involved in the aetiopathogenesis of this disease.

Introduction

In 1997, a newly emerged disease of the ovine digit was observed in the UK, the lesions of which led to severe clinical signs in affected animals (Harwood et al., 1997). The distinction between this disease and ovine foot rot was made by the differences in clinical appearance, the failure to respond to conventional foot rot therapies, and the isolation of Treponema spp. from the lesions, with and without concurrent detection of the causative agent of foot rot, Dichelobacter nodosus (Naylor et al., 1998; Davies et al., 1999; Lewis et al., 2001). The disease was named contagious ovine digital dermatitis (CODD) (Davies et al., 1999) and further work has since identified three Treponema phylogroups to be associated with clinical disease, namely Treponema medium/Treponema vincentii-like, Treponema phagedenis-like and Treponema pedis (Sullivan et al., 2015). These same three Treponema phylogroups are reported to be the cause of bovine digital dermatitis (BDD) (Evans et al., 2008), although not all BDD lesions may necessarily contain all three phylogroups (Evans et al., 2009).

Recently, the clinical presentation of CODD was described in detail for the first time, and a five-point lesion grading system was proposed (Angell et al.,...
In that study, the range of lesions was organized into a clinical progression of disease such that lesions progressed from grade 1 to 5. Briefly, the disease begins at the coronary band and extends distally, resulting in progressive, and eventually total, separation of the dorsal hoof wall. The lesions may resolve and new horn eventually replaces the horn lost in the fulminant stage of the disease, with some deformity of the regrown hoof. To date, there has been no histopathological characterization of these lesions or immunohistochemical investigation of the presence of *Treponema* spp. associated with the pathological changes.

In cattle, immunohistochemistry (IHC) has been used to identify *Treponema*-like organisms in BDD lesions, and these are associated with hair follicles and sebaceous glands (Evans et al., 2009). In the present study, IHC was used to investigate the presence/absence of CODD-associated *Treponema* spp. It was considered that *Treponema* spp. would more likely be identified in earlier grades of lesion, particularly those of grade 1. The organisms may persist throughout all of the stages of the clinical disease, but might not be identifiable due to competition by secondary invaders, tissue necrosis or damage/removal by the immune system.

The aims of this study were: (1) to describe the histopathological changes observed for each grade of clinical lesion and to investigate whether these grades reflected a progression of disease, and (2) to investigate whether the spirochaetes of the three phylogroups, *T. medium*/*T. vincentii*-like, *T. phagedenis*-like and *T. pedis*, were associated with clinical disease.

**Materials and Methods**

The study protocol was approved by the University of Liverpool Ethics Committee (VREC 13).

**Sampling**

In a previous study, a novel five-point lesion grading system was proposed to describe clinical cases of CODD (Angell et al., 2015). In that study, clinical cases deemed typical of each lesion grade were obtained and the digits were sampled post mortem for further radiographic analysis. These digits were removed immediately post mortem and placed in 10% neutral buffered formalin. These same digits were used in the current study. In addition, two sheep were purchased from a farm with no clinical history or evidence of CODD and digits from these were used as negative controls, together with interdigital skin from the footpad of a dog with exudative interdigital pyoderma.

Fifteen digits were used, including the two normal digits from the two negative control sheep, a clinically normal digit from a sheep that had CODD in other digits in other feet, five digits with lesions of clinical grade 1, two digits with grade 2 lesions, two digits with grade 3 lesions, one digit with a grade 4 lesion and two digits with grade 5 lesions.

**Histopathology**

Each digit was sectioned sagittally to obtain a longitudinal slice of approximately 3–5 mm incorporating hoofhorn, phalangeal bones and soft tissues up to and including the proximal phalanx. In all cases the following tissue samples were obtained (Fig. 1): (1) distal digital skin including the coronary band, (2) dorsal horn with laminae, (3) solar horn with laminae, and (4) the distal phalanx. These tissues were embedded in paraffin wax. Blocks containing horn underwent a softening pretreatment with hair...

removal lotion (Nair Hair Removal Lotion; Church & Dwight, Folkestone, UK) and blocks containing bone were decalcified using a decalcification product (Calci-Clear; National Diagnostics, Hessle, UK), respectively. These were then sectioned into 5 μm slices and stained with haematoxylin and eosin (HE). A selection of tissues from different digits with necro-suppurative lesions with numerous bacterial colonies were also stained by the Warthin–Starry method.

**Immunohistochemistry**

IHC was employed to investigate the presence of the three CODD-associated *Treponema* spp. in tissue samples using a polyclonal antibody raised in a rabbit (Evans *et al.*, 2009). Sections were dewaxed using a series of xylene and ethanol baths followed by pretreatment with H<sub>2</sub>O<sub>2</sub> in methanol (6 ml of 30% H<sub>2</sub>O<sub>2</sub> in 360 ml of methanol) to block endogenous peroxidase activity. Antigen retrieval was performed using bacterial proteinase type XXIV (Sigma; Poole, Dorset, UK) for 5 min before blocking with normal goat serum for 10 min. The primary antibody (1 in 4,000 dilution) was incubated overnight and then slides were washed and incubated with secondary goat anti-rabbit antibody (1 in 100 dilution) for 30 min before being washed again. An avidin–biotin complex method was used to detect binding. The slides were then counterstained with haematoxylin. Following optimization and examination under low power to survey tissue areas, a grading system of no labelling (0), mild (1), moderate (2) or strong (3) labelling was used to give an indication of the varying intensity of the *Treponema* spp. antigen detection. None of

the control tissues exhibited any positive immuno-
labelling and the bacteria in the canine skin sample
were not labelled.

**Results**

Details of each lesion are summarized in Table 1; key
features from each grade of clinical lesion grade are
summarized below.

*Clinically Normal Digits and Negative Controls*

There was mild eosinophilic and lymphoplasmacytic dermatitis of the distal digital skin. No signif-
icant change was observed in the hoof. There were
no organisms detected by Warthin–Starry stain
and there was no specific immunohistochemical
labelling. Representative images are shown in
Fig. 2.

*Clinical Grade 1*

The distal digital haired skin and coronary band ex-
hibited mild to severe, multifocal, periadnexal to peri-
follicular lymphoplasmacytic infiltration within the
superficial dermis, in some cases extending into the
deep dermis. In some digits there was moderate
epidermal hyperplasia and orthokeratotic and/or
parakeratotic hyperkeratosis. Bacterial colonies of
variable morphology, with haemorrhage and an infil-
trate of neutrophils, were sometimes present at the
coronary band. At the coronary band and distally

![Fig. 3. Tissues from a CODD lesion of clinical grade 1. HE (a, c and e); IHC (b, d and f). (a) Skin/coronary band with moderate, multi-
focal, periadnexal/peri follicular lymphoplasmacytic derma ti tis with hyperplasia and orthokeratotic hyperkeratosis (left of the im-
age). (b) Very mild background immunolabelling in the superficial stratum corneum. (c) Diffuse severe erosion of the dorsal horn with suppurative inflammation, haemorrhage and oedema. (d) Mild extracellular labelling of the exudate with strong labelling of
the superficial eroded dorsal horn. (e) Superficial inflammatory exudate and intracorneal pustules in the dorsal horn adjacent to the
coronary band. (f) Extracellular labelling of eroded material of skin/dorsal horn at coronary band region, together with labelling
within a fissure extending deeper into the epidermis, becoming more intense at the deepest point.](image-url)
in the superficial dorsal hoof horn there was strong extracellular immunolabelling. Often there was strong and specific immunolabelling of organisms with clear \textit{Treponema} spp. morphology, admixed with the neutrophilic infiltrate, often in the hyperkeratotic regions, at the sites of hoof wall detachment and between the cells of the stratum corneum and stratum spinosum (Fig. 3).

Within the subcorneal epidermal laminae there was mild to severe, multifocal, dermal perivascular lymphoplasmacytic infiltration, sometimes with pustules associated with degenerate keratinocytes. In some digits the proximal dorsal hoof horn (stratum corneum) had become detached from the remainder of the epidermis. Where the horn had separated, the eroded epidermis was lined by a superficial layer of proteinaceous debris, degenerate neutrophils, necrotic keratinocytes and bacterial colonies of variable morphology. The neutrophils extended into the remaining epidermis and were present in the dermal and epidermal laminae.

In the regions of epidermal erosion and suppurative inflammation, superficially there were large, multifocal areas of strong immunolabelling with large numbers of organisms exhibiting clear \textit{Treponema} spp. morphology. These were located extracellularly between the (sometimes sloughed) keratinocytes of the stratum corneum and stratum spinosum. Occasionally, there were small areas of strong extracellular labelling with several organisms exhibiting \textit{Treponema} spp. morphology in the deeper epidermis. Representative images are shown in Fig. 3.

**Clinical Grade 2**

Within the distal digital haired skin there was moderate to severe epidermal hyperplasia with rete ridge formation and orthokeratotic hyperkeratosis. There was moderate, multifocal to diffuse, lymphoplasmacytic infiltration of the superficial and mid dermis, becoming progressively more severe towards the coronary band. No immunolabelling was observed in the distal digital skin.

There was complete loss of the superficial cornified layer (horn) of the proximal dorsal hoof wall, with replacement by a band of degenerate neutrophils, fibrin, necrotic debris, haemorrhage and numerous colonies of coccobacilli. The epidermal laminae were markedly infiltrated by the suppurative inflammatory process, which extended into the dermal laminae becoming mixed with a moderate to severe lymphoplasmacytic infiltrate. In the superficial stratum corneum there were numerous groups of bacteria with coccoid, rod and spirochaetal morphology.

There were large multifocal to coalescing areas of strong extracellular immunolabelling in the eroded dorsal horn, which extended to the dorsal laminae and was admixed with large numbers of positively-labelled organisms with clear \textit{Treponema} spp. morphology. This was mostly observed superficially.
in areas of suppurative inflammation, but strong extracellular immunolabelling was also found deep within the horn.

In the caudal solar horn and laminae there was background mild lymphoplasmacytic infiltration throughout the superficial dermis. In the more distal sections, the horn was separated from the remainder of the epidermis. Superficially, there was marked infiltration of neutrophils with fibrin, necrotic debris and haemorrhage. The dermal laminae were similarly infiltrated by neutrophils, mixed with lymphocytes and plasma cells. Subjacent to the epidermis was a lymphoplasmacytic band with fewer neutrophils, throughout the superficial dermis and almost obscuring the dermo-epidermal junction. There was a distinct boundary (distal to caudal) between the severely affected tissue and relatively mildly affected tissue, which exhibited an intact cornified epidermis and mild lymphoplasmacytic and very mild supplicative dermatitis of the dermal laminae. No immunolabelling was observed in the caudal and solar horn/laminae.

In the distal phalanx, in one digit, the cambium layer of the periosteum subjacent to the dermal inflammation consisted of a continuous row of plump (activated) osteoblast-like cells. There were no organisms detected in the distal phalanx by Warthin–Starry staining and no immunolabelling was observed. Representative images are shown in Figs. 4 and 5.

Clinical Grade 3

The histological appearance was similar to that of the grade 2 lesions, although there was moderate, homogeneous non-specific immunolabelling at the level of the coronary band. The stratum corneum of the dorsal hoof horn was markedly and irregularly thickened where present, but in some areas was eroded or partially detached exposing the subcorneal layers of the epidermis, which was, in some areas, expanded by intracorneal pustules. The eroded tissues and subjacent dorsal laminae exhibited histological changes similar to those of the grade 2 samples, also demonstrating strong extracellular immunolabelling, but there were fewer organisms exhibiting clear Treponema spp. morphology.

The solar horn was thickened by moderate diffuse orthokeratotic hyperkeratosis. Within the solar laminae and subjacent dermis there was moderate, multifocal to coalescing lymphoplasmacytic infiltration. There was no evidence of suppuration within the solar horn or associated laminae or dermis.

The periosteum on the dorsal aspect of the distal phalanx was activated with mild to moderate new bone growth dorsally. Within the adjacent dermis there were mild lymphoplasmacytic infiltrates, together with variably sized collections of activated fibroblasts. No immunolabelling was present. Representative images are shown in Fig. 6.

Clinical Grade 4

There was moderate epidermal hyperplasia and orthokeratotic hyperkeratosis of the distal digital haired skin. There was mild multifocal lymphoplasmacytic infiltration of the dermis, but the epidermis of the coronary band appeared unaltered. In the skin and coronary band there were numerous groups of bacteria with mostly coccoid and rod morphology superficially, but no immunolabelling was observed.

The superficial cornified layer of the dorsal hoof horn exhibited extensive areas of marked infiltration by neutrophils admixed with fibrin and necrotic debris, together with proliferation of well vascularized fibrous tissue (granulation tissue) with plump fibroblast and endothelial cell nuclei. Superficially within the suppurrative and necrotic areas there were numerous groups of bacteria with mostly coccoid, rod and spirochaetal morphology, and there was strong extracellular immunolabelling and labelling of small numbers of organisms exhibiting clear treponemal morphology. These areas were not as extensive and there appeared to be fewer organisms than in grade 1 and 2 lesions, and there was no involvement of the solar horn and laminae. The dorsal epidermal laminae were hyperplastic and the dermal laminae and sub epidermal dermis exhibited background mild multifocal lymphoplasmacytic infiltration.

Within the connective tissue between the dorsal hoof wall and the distal phalanx, there was moderate, multifocal lymphoplasmacytic infiltration within moderately well vascularized, dense, fibrous connective tissue with plump fibroblast nuclei (mature granulation tissue). The dorsal surface of the distal phalanx was highly irregular with multifocal...
projections extending from the bone into the over-lying connective tissue. The projections were well mineralized closer to the bone, but more distally were predominantly fibrous, and distally they were poorly demarcated from the surrounding connective tissue and had no periosteal lining. There were islands of osseous tissue separate from the distal phalanx within the fibrous connective tissue. The distal tip of the distal phalanx was partially lost in one of the digits and replaced by fibrous connective tissue. Where present, the periosteal cambium exhibited hyperplastic osteoblast-like cells. No immunolabelling was present in the distal phalanx. Representative images are shown in Fig. 7.

![Fig. 7. Tissues from a CODD lesion of clinical grade 4. HE (a, c, e and g); IHC (b, d, f and h). (a) Hyperplastic dermal laminae and granulation tissue of the dorsal horn. Contagious Ovine Digital Dermatitis

Clinical Grade 5

In the distal digital skin/corony branch there was a mild diffuse hyperplasia, with mild diffuse orthokeratotic hyperkeratosis together with mild to moderate multifocal lymphoplasmacytic infiltration within the superficial and mid dermis. In the necrotic debris sloughed from the distal skin there were small bacterial colonies mostly with indistinguishable morphology. No immunolabelling was observed in the distal digital skin/corony branch or the sloughed necrotic debris.

The cornified layer of the dorsal horn was largely intact, but exhibited numerous areas of nucleation of corneal keratinocytes. There were multifocal intracorneal aggregates of degenerate neutrophils and necrotic cells admixed with haemorrhage and multifocal small bacterial colonies mostly with coccoid, rod or indistinguishable morphology. The epidermal laminae were shortened, thickened and often fused into wide bands. There was mild to moderate multifocal lymphoplasmacytic infiltration, together with active fibroblasts. No immunolabelling was observed in the dorsal horn.

The dorsal margin of the distal phalanx was mild to moderately uneven with numerous small spicules. The cambium layer of the periosteum contained numerous plump osteoblast-like cells. No immunolabelling was observed. Representative images are shown in Fig. 8.

Discussion

The sampling strategy used in this study ensured that fresh specimens of clinical cases were obtained and placed in fixative within minutes of death. However, due to on-farm practical constraints and in order to focus resources, this meant that the number of lesions in each grade was small and was not uniform. However, this bias is not considered to invalidate the histopathological description due to the consistent changes noted across the different lesion grades, nor invalidate the immunolabelling due to the consistent...
and predictive pattern of reaction. Attention was focused on the early lesions (i.e. grade 1) as clinically these lesions appear to progress to grades 2–5 (Angell et al., 2015) and it was considered that information from these early lesions would add more in understanding the aetiopathogenesis of the disease.

Furthermore, in considering the associations between Treponema spp. and the pathological changes present, and their putative role as causal agents, it was considered important to identify whether the bacteria could be detected in early lesions and thus help to determine their role in the aetiopathogenesis of CODD.
In the tissues obtained from the clinically normal negative control animals, there was a mild, perivascular, dermal, mainly lymphoplasmacytic infiltrate. To our knowledge, this ‘background infiltrate’ has not been reported in sheep before and we are not aware of any similar reports in other species. Indeed, there has been limited published histological investigation of the ovine digit and as such this finding should be interpreted cautiously. It is not necessarily surprising that this part of the skin, being exposed to wet conditions and persistent low-level trauma, should have a low-grade chronic inflammatory reaction present in clinically normal animals. However, in viewing and interpreting the pathological changes described in this paper, this background infiltrate should be borne in mind.

This is the first time to the knowledge of the authors that CODD lesions have been documented histologically and the first time immunohistochemical techniques have been used to determine the presence and location of Treponema spp. in ovine feet.

In an earlier paper (Angell et al., 2015), it was suggested that the clinical lesion grades may form a progression of disease such that CODD may initially present as a grade 1 lesion and then progress through the other grades. The histological observations made in this current study appear to support this theory, in that acute changes were first observed at the coronary band, followed by very severe necrotizing and fibrino-suppurative lesions with separation of the horn in tissues from grade 2 and 3. Tissues from grade 4 lesions showed signs of chronicity (e.g. granulation tissue), but with suppurative lesions still present, and grade 5 lesions showed evidence of healing, albeit with mild intracorneal suppurative changes still present in some cases. The histological changes in the low-grade lesions clinically appear to commence at the coronary band and then the lesion appears to progress distally down the dorsal horn while the initial site (coronary band) heals. As such, the clinical and histopathological descriptions from both this current study and the previous clinical description appear well correlated and this may support the use and reliability of the CODD lesion grading system.

In cattle, BDD-associated Treponema spp. have been observed in and around hair follicles and sebaceous glands, and these structures have been suggested as a potential route of entry/exit of the bacteria into the tissues (Evans et al., 2009). In the current study, the distal digital skin above the coronary band exhibited progressive lymphoplasmacytic dermatitis with epidermal hyperplasia, but in no cases was the very destructive suppurative lesion present in this location. Furthermore, no Treponema-like organisms were observed in hair follicles or sebaceous glands. This may suggest that in sheep the pathological processes target the keratin of the hoof horn more specifically.

In this study it was considered that CODD-associated Treponema spp. would be observed in clinically active lesions, but possibly absent in healed (grade 5) lesions, which appears to be the case in these samples. The immunolabelling showed microorganisms with morphology consistent with Treponema spp. predominantly present extracellularly between the keratinocytes. Semi-quantitatively, there appeared to be stronger immunolabelling in the earlier lesions (i.e. grades 1 and 2) compared with lesions of grades 3 and 4, and certainly greater numbers of organisms with Treponema-like morphology were readily identified in the earlier lesions. When present, these organisms appeared to penetrate for a short distance between the keratinocytes. These findings demonstrate that Treponema-like organisms are associated with active lesions, and it may be that they are involved in the initiation and/or propagation of the disease. This was further supported by the absence of Treponema-like organisms in healed (grade 5) lesions.

It was beyond the scope of this study to determine the causal nature of the Treponema-like organisms identified; however, the distribution within the tissues strongly suggests that they are causally involved to some extent. For example, in Fig. 4 the immunolabelling is stronger at the leading edge of the fissuring in (b) and (f), and in image (e) the immunolabelling is strongly associated with the pathological separation of the superficial dorsal horn from the remaining epidermis. Furthermore, intracorneal pustules were observed in many sections and the examples presented here demonstrate a possible association of Treponema spp. immunolabelling with these intracorneal pustules.

In the sections with strong, specific immunolabelling, there were extensive areas of amorphous positively-labelled material, centred on the exudates in the areas of sloughed horn. The Treponema spp. organisms were often embedded within this exudate, but the exact nature of the homogeneous labelling is unclear. It could either represent excreted Treponema spp. antigen, either free or bound by local tissues, or antigen released as a result of organism degeneration. It is possible that Treponema spp. organisms are lysed as a result of enzymes secreted during necrosis and/or inflammation or as a result of the strong host immune response (Dhawi et al., 2005). This detection of Treponema spp. antigen in tissues, and the relative absence of intact Treponema spp. in later-stage CODD lesions, again supports the hypothesis of a potential key role for the organisms in the initiation of
CODD lesions. The exudate in these lesions appeared to label strongly and specifically with the anti-\textit{Trepomonema} spp. antibody, and negative control tissues (i.e. unaffected sheep feet and exudative pyoderma from a dog) were negative with only very faint background labelling, which in the case of the dog was also predominantly intracellular.

A further possibility is that in more chronic lesions with avulsion of the hoof horn capsule, the \textit{Trepomonema}-like organisms are fewer in number due to them being shed with the keratin. Further testing is required in order to investigate these observations more fully.

In conclusion, CODD remains a challenge to the sheep industry. This study documents for the first time the histopathological changes associated with clinical lesions of each grade and provides clear evidence of how the lesions develop as the disease progresses. Furthermore, the presence of \textit{Trepomonema}-like organisms associated with active lesions adds weight to the hypothesis that these bacteria are involved in the aetiopathogenesis of the disease.

**Acknowledgments**

This study was supported by a grant from the British Veterinary Association Animal Welfare Foundation. The funder had no role in study design, collection, analysis and interpretation of data, in writing the report, or in the decision to submit for publication. We gratefully acknowledge the farmers involved in the study for their compliance in providing their sheep. Thanks to L. Sullivan and E. Swan for assistance in collecting the samples, and to V. Tilston, A. Bertram, J. Haigh and K. Joyce for their assistance in processing the tissue samples for histopathology. The first two authors contributed equally to this manuscript.
