Abstract

The interesting point of this work is to increase the amount of produced H\textsubscript{2} in order to improve the energy density of the H\textsubscript{2} generator system. For this, one of the main challenges is to increase the NaBH\textsubscript{4} concentration of the cartridge solution thus avoiding the drawbacks induced by NaBO\textsubscript{2} crystallization, but also to control the stability of this solution, it means add sodium hydroxide to limit the NaBH\textsubscript{4} self-decomposition, thus stabilizing the system. This paper shows the two aspects of the cartridge lifetime analysis: the overall order reaction of spontaneous hydrolysis reaction of alkaline aqueous NaBH\textsubscript{4} solutions as function of NaOH concentration and the operation temperature range of the cartridge; an unequivocal understanding of the NaBO\textsubscript{2} crystallization process and more specifically the delimitation of the homogeneous liquid phase domain in the quaternary system NaBH\textsubscript{4}–NaBO\textsubscript{2}–NaOH–H\textsubscript{2}O.

The rise of portable electronic devices, brings to the fore the crucial issues of power supply. The foreseeable evolution in functionalities and utilizations, as regards portable electronic devices, together with the introduction of novel electronic components, entail considerable changes in requirements, in terms of power consumption and autonomy (Fig. 1) [1].

A hydrogen system for its production and distribution depends on the type of hydrogen storage used. This gas has a very low volumetric energy density, so it is difficult to store a sufficient amount of it in a small and light enough vessel. In fact, a safe, efficient and economical method of storing hydrogen must be available to turn viable a hydrogen economy based on renewable resources [2-4].

Hydrogen generation by means of the hydrolysis of borohydrides is a promising technology for portable fuel cells [5-8]. Particularly, sodium borohydride (NaBH₄) presents many advantages for that purpose. For example, NaBH₄ solutions are non-flammable thus yielding safe processes; the rate of H₂
The hydrolysis of NaBH₄ in water to produce H₂ gives by-products, NaBO₂·yH₂O, hydrated sodium borate compounds according to the sodium borohydrate hydrolysis reaction Eq. 1, with the pseudo hydration degree y = 0, 1/3, 2/3, 2 or 4 [9].

\[ NaBH_{4(s)} + (2 + y)H_2O_{(l)} \Leftrightarrow 4H_{2(g)} + NaBO_{2(y)}H_2O_{(s)} \]  

(1)

The exponential growth of the NaBH₄ hydrolysis rate with decreasing pH is known for weakly alkaline concentrations. The spontaneous hydrolysis of pure NaBH₄ solution is an acid-catalysed reaction, H₃O⁺ ions are formed in-situ. A detailed mechanism based on the substitution of B-H bonds by B-OH in aqueous solutions leading to the formation of borate and hydrogen, has been proposed by Mochalov et al. [10]. This mechanism presents the steps of the hydrolysis reaction and the formation of different intermediates.

The hydrolysis would be a multistep process involving hydroxyborate intermediates BH₄₋(OH)ₓ (x from 1 to 3) [11]. Mochalov et al. have verified the formation of these hydroxy derivatives by subjecting a solution of NaBH₄, which was undergoing hydrolysis, to chromatographic separation on paper under conditions of a strongly alkaline medium.

The reactions (Eq. 2) show the H₃O⁺ catalyzed hydrolysis of (BH₄)⁻ and the formation of the first intermediate BH₃(OH)⁻; z = 1. The formation of BH₃ from (BH₄)⁻ involves an activated complex. The Eq. 2 presents the steps of activated complexes formation, the limiting steps of the hydrolysis’s mechanism [11].

The participation of the OH⁻ ions in the hydrolysis process sets in with the stage for the formation of borine (diborane), BH₃, which being a strong Lewis acid, readily takes on OH⁻ to form a more stable ion, BH₃OH⁻. Mochalov et al. affirms that these reactions take place very rapidly since the particles BH₃, BH₂OH and BH(OH)₂ are most unstable and very reactive. So, it may be seen that an aqueous solution of borohydride is a very complex system of many components [10].

\[ BH_4^{-}_{(aq)} + H_3O^+_{(aq)} \rightarrow BH_3_{(aq)} + H_2O_{(l)} + H_2_{(g)} \]

\[ BH_3_{(aq)} + OH^-_{(aq)} \rightarrow BH_3OH^-_{(aq)} \]  

(2)

The theoretical hydrogen yield in the reaction in Eq. 1 is 10.8 w% if the selectivity of by-products is displaced to the anhydrous borate (y = 0). However, anhydrous borate is obtained only under extreme temperature or pressure conditions, which are incompatible with portable applications. Moreover, water in excess is required to solubilize the reaction by-product in order to avoid any crystallization phenomena on the catalyst surface, a condition which may affect the hydrogen generation rate. Consequently, an unequivocal understanding of the NaBO₂ crystallization process remains to be a key factor. It is not reliable to approximate the H-content by simply assuming the theoretical yield and, thus being required to consider equilibrium and thermophysical properties such as the solubility limit, density, viscosity and the formation of crystalline by-products [12].

The present paper has the intent to study two aspects of the cartridge lifetime. Firstly, this work presents an overall order reaction of spontaneous hydrolysis of alkaline aqueous NaBH₄ solutions
(14.0 w%) for NaOH concentration of 4.0 w% at 50 °C. Secondly, a study about the NaBO$_2$ crystallization process will be present, more specifically, the delimitation of the homogeneous liquid phase domain in the quaternary system which represents the solution during the cartridge operation.

2. Material and methods

2.1. Solutions stability: Spontaneous sodium borohydride hydrolysis

Hydrogen generation is obtained by the measurement of the relative pressure in a stainless bench (Swagelok) (Fig. 2).

The molar volume of a perfect gas is 24000.0 cm$^3$.mol$^{-1}$ at $T = 20$ °C and $P = 1.0$ atm. The pressure variation of the hydrogen generation has been measured at these conditions. The pressure sensor accuracy is 0.3% of the sensor range, for the experiments at 20 °C the sensor range is from 0 to 5 bar ± 0.0015, and, for the experiments at 50 and 70 °C it is from 0 to 20 bar ± 0.006.

The volume of generated hydrogen, considering an ideal gas, is calculated by the Eq. 3.

$$V_{H_2 prod} = n_{H_2 prod} \frac{V}{molar} \frac{\Delta P V_{free} V_{molar}}{R.T} ;$$

with $\Delta P = P_{mes} - P_{ref}$ (3)

For each solutions preparations, anhydrous NaOH (Sigma-Aldrich®, ≥ 99.99 % purity, pellets, n° CAS: 1310-73-2) and NaBH$_4$ (Sigma-Aldrich®, 98 % purity, caplets, n° CAS: 16940-66-2) are stored and handled in an argon-filled glove box in order to prevent hydration, thus avoiding moisture and subsequent hydrolysis, in the case of the NaBH$_4$. Deionized water is introduced at room temperature in order to avoid spontaneous decomposition of NaBH$_4$ in water. After homogenization of the solution, a sample is added to the reactor of the stability bench (Fig. 2).

![Fig. 2. Stability bench for hydrogen generation by spontaneous NaBH$_4$ hydrolysis.](image-url)
2.2. Solubility in the quaternary system NaBH₄–NaBO₂–NaOH–H₂O

For each quaternary mixture preparations, anhydrous NaOH (Sigma-Aldrich®, ≥ 99.99 % purity, pellets, n° CAS: 1310-73-2) and NaBH₄ (Sigma-Aldrich®, ≥ 99% purity, powder, n° CAS: 16940-66-2) are stored and handled in an argon-filled glove box in order to prevent hydration, thus avoiding moisture and subsequent hydrolysis, in the case of the NaBH₄. Deionized water is introduced at room temperature in order to avoid spontaneous decomposition of NaBH₄ in water. Sodium borate can be by heat treatment of the NaBO₂·2H₂O (ACROS Organics, 98.5 % purity, n° CAS: 10555-76-7) in order to obtain the NaBO₂ anhydrous. In this latter case, commercial borate (a mixture of NaBO₂·4H₂O and NaBO₂·2H₂O) is heated at 300 °C for 72 hours in a tubular oven under argon flow. Afterwards, anhydrous borate is confirmed by X-ray diffraction analysis. Then, for each mixture, a solution of 30-50 g is prepared in order to have enough liquid sample for chemical analysis after centrifugation and decantation processes. The experimental procedure is as follows: Weigh the desired amount of anhydrous NaOH, NaBO₂ and NaBH₄ in a plastic centrifuge tube. Add the exact amount of water. Introduce a stir bar in the solution tube and, then, insert it in a thermostated reactor, where the solution is stirred during 30 minutes which is sufficient to reach the equilibrium state. Thermostated centrifugation of the solution until obtaining the separation of phases (liquid + solid). Lastly, in addition, a thermostated decantation is performed before chemical analysis to further attain a complete separation of phases.

In order to determine the solubility limit, the liquid phase is analysed by acid-base titration with HCl (0.5 mol.L⁻¹). A classic acid-base titration curve is obtained with two equivalence points, the first one corresponding to NaOH while the second one corresponds to NaBO₂. NaBH₄ content in the saturated liquid phase of quaternary solutions is quantified by means iodometric titration. Besides establishing the NaOH amount; acid-base titration gives the total NaBO₂ amount (i.e. the NaBO₂ content in the saturated solution together with the amount produced by consumption of NaBH₄ during HCl titration). The NaBO₂ amount present in the saturated liquid phase solution is obtained then by difference.

The determination of the solid phase in equilibrium with the liquid is performed by means of X-ray diffraction (XRD). XRD analyzes are performed on the Bruker D8 Advance diffractometer, in air, at room temperature. This diffractometer has a Bragg-Brentano configuration, used in reflection mode, with a θ-2θ installation and a copper anticathode tube (λ Kα₁ = 1.5406 Å - λ Kα₂ = 1.54439 Å). The sample is prepared by removing some solid phase from the biphasic solution. The solid sample is dried with a filter paper to remove the solution. Then it is deposited on a specific holder. Kapton® is used to prevent hydration of the solid during sample handling and analysis.

3. Results

3.1. Solution stability: Spontaneous sodium borohydride hydrolysis

3.1.1. Temperature dependence

The Fig. 3 compares the volume of hydrogen generation at different temperatures: 20, 50 and 70 °C for 3.0 w% NaOH and NaBH₄ composition of 14.0 w% (initial conditions). The hydrogen generation volume increases as temperature increases at a fixed NaOH concentration, as expected.
The Fig. 3 illustrates that the volume of generated hydrogen is strongly dependent on temperature and the behavior of this curve changes enormously for high temperatures, and this behavior justifies a carefully evaluation of the kinetic parameters, in particular for a long operating time.

3.1.2. Empirical Rate Equations of NaBH₄ hydrolysis

Thermal decomposition of borohydride in alkaline solution is assumed by different authors to be a first-order reaction, as a function of NaBH₄ [13]. It is evident it is a complex mechanism like it has been presented by Mochalov et al.

At this work, the pH of the solutions is always superior to 13.0 because of the presence of the stabilizer agent, NaOH, it means, a non-catalytic hydrolysis, with a slow pH-independent path. In this case, there is no data about the mechanism in the literature, and an empirical rate equation of nth order has been applied with the intent to fit the data with an nth-order rate equation of the form:

\[- r_A = - \frac{dC_A}{dt} = k.C_A^n \tag{4} \]

Some hypotheses for the overall order of the hydrolysis reaction, \( n \), have been evaluated. The Eq. 5 presents the variation of NaBH₄ mol number, \( N_A \), as a function of time, for a constant volume of solution during hydrolysis reaction.

\[ V_{sol} = cte \text{ then: } - \int \frac{dN_A}{N_A^n} = k.V_{sol}^{(1-n)} \int dt \tag{5} \]

\( n = 0, 1, 2, 5/2, 3 \)
Churikov et al. established some characteristics of the kinetic curve of borohydride hydrolysis in strongly aqueous solutions (content of NaOH from 8.24 to 27.32 w%). A fast initial decomposition by a linear law (zero-order reaction) with a gradual transfer to slow decomposition (the logarithmic law) at middle stages (first-order reaction) [13].

In a first moment, the hypothesis of a first-order reaction, for hydrolysis conversion < 40 %, has been evaluated (Eq. 6). The Table 1 shows the kinetic constant, $k$, as a function of [NaOH] for the subsequent retarded decomposition regime described by the logarithmic law. For the experimental results at 50 °C, 40 % conversion is achieved around 200 hours, although at 70 °C, 40 % conversion is achieved around 30 hours.

$$\ln \left( \frac{N_{0\text{in}}}{N_{\text{in}}} \right) = f(t)$$ (6)

After this hypothesis of a first-order reaction for hydrolysis conversion < 40 %, it has been decided to evaluate an overall order reaction between 1 and 3 to describe the totally of the experimental curve at 50 °C, ie for a period of about 700 hours of continuous operation. For this evaluation, the NaOH content of 4.0 w% has been chosen.

The variation of the number of moles versus time has been expressed for different overall order reaction and a linear relation is expected. For this purpose, the hypotheses of an overall order reaction have been evaluated. The Fig. 4-9 illustrate the relation between the variation of NaBH$_4$ mol number as a function of time submits to the hypotheses of order reaction: 1, 2, 3 and 5/2, respectively.

![Fig. 4. Borohydride decomposition degree as a function of time at 50 °C and 4.0 w% NaOH, an overall first-order hypothesis.](image-url)
The Fig. 4 presents the hypotheses of first-order reaction and a non-linear relation has been obtained, it means that the totally of the curve can not be described as a first order-reaction, even though different authors have affirmed this. The hypotheses of second and third order have been evaluated and it is possible to note that a better linear correlation is obtained to an overall order reaction between 2 and 3 (Fig. 5 and 6, respectively). An overall 5/2 order reaction presents a satisfactory linearization for the experimental curve at 50 °C, with a good correlation coefficient, $r^2 = 0.9998$ (Fig. 7).

3.2. Solubility in the quaternary system NaBH₄–NaBO₂–NaOH–H₂O

To determine the solubility limit of the solid phases in the quaternary system, an isopleth section has been defined considering a constant NaOH composition. The Figure 8 depicts the quoted isopleth section of the quaternary system.

![Isoplethic section](image)

**Fig. 8.** Isoplethic section for a constant NaOH composition of the quaternary system at isobaric and isothermal conditions.

Figure 9 presents detailed experimental results of the solubility limit at 0 °C and 20 °C for the quaternary system at the isoplethic section.

The isotherm at 20 °C in Figure 9 illustrates three biphasic regions: Liquid + NaBO₂·4H₂O, Liquid + NaBO₂·2H₂O, and Liquid + NaBH₄·2H₂O; and two triphasic regions: L₁ + NaBO₂·4H₂O + NaBO₂·2H₂O and L₂ + NaBO₂·2H₂O + NaBH₄·2H₂O. Although the isotherm at 0 °C illustrates two biphasic regions: Liquid + NaBO₂·4H₂O and Liquid + NaBH₄·2H₂O; and one triphasic region: L₀ + NaBO₂·4H₂O + NaBH₄·2H₂O. All these solid phases have been confirmed by XRD.

![Solubility limit](image)

**Fig. 9.** Solubility limit at 0 °C (black) and 20 °C (blue) of the quaternary system NaBH₄–NaBO₂–H₂O–NaOH (mass fraction in Jänecke coordinates, w) for an isopleth section considering a constant NaOH composition (P = 1 atm).
4. Conclusion

This work contributes for a lifetime analysis of a hydrogen generator involving the stability of the solution and the solubility limit of the quaternary system NaBH₄–NaBO₂–NaOH–H₂O.

An initial part of this work proposes a kinetic analysis of experimental curves of the spontaneous hydrolysis of concentrated NaBH₄ solutions with the stabilizer agent NaOH. The hypothesis of a first-order reaction for a hydrolysis conversion inferior to 40 % has been evaluated at 50 and 70 °C and for 2.0, 3.0 and 4.0 w%. NaOH. An overall 5/2 order reaction has been revealed for the entire experimental curve at 50 °C. A fractional order of a chemical reaction gives the evidence of a kinetic mechanism, which allows to reaffirm that an aqueous solution of borohydride is a very complex system of many components.

A second part presents the experimental results of the solubility limit at 0 °C and 20 °C of the quaternary system for a constant NaOH concentration, showing the decrease in the volume of liquid by lowering the temperature.
