Left anterior descending coronary artery dissection after blunt chest trauma: Assessment by multi-detector row computed tomography

Tarek Smayra, MD, a Roger Noun, MD, b and Carla Tohmé-Noun, MD, a Beirut, Lebanon

A 17-year-old male patient with no previous heart disease was sent to our institution for multi-detector row computed tomography (MDCT) coronary angiography following posttraumatic myocardial infarction.

Clinical Summary
Two months earlier, this unrestrained driver had an accident and sustained steering wheel injury as well as head trauma and multiple fractures. He was admitted to the intensive care unit for loss of consciousness at the scene and had his fractures repaired. Follow-up was unremarkable and he was discharged 1 month after the accident. A few days later, he presented with chest pain associated with ST elevation in the precordial leads on electrocardiogram and high serum level of creatine kinase with a positive MB fraction. Transthoracic echocardiography showed moderate hypokinesis of the septum and the anterior wall. MDCT coronary angiography was carried out using a 64-slice LightSpeed VCT (General Electric Healthcare, Little Chalfont, UK) with 0.625-mm collimation, cardiac gating, and intravenous injection of iopromide 370 mg (milligrams of iodine)/mL (Ultravist, Schering AG, Germany). It showed septoapical and anteroseptal subendocardial linear hypodensity (Figure 1) associated with hypokinesis on cine mode, corresponding to infarcted area of the myocardium. Left ventricle ejection fraction was 43%. Coronary artery analysis showed a left dominant distribution with arterial dissection beginning at the ostium of the left anterior descending coronary artery (LAD) and extending 10 mm distally with a dilated false lumen giving rise to a septal artery and slightly narrowing the true lumen (Figure 2). The patient had a coronary artery bypass, using the left internal thoracic artery to LAD. A year later, he is doing well and living a normal active life.

Discussion
Coronary artery dissection is a well-known but unusual complication of blunt chest trauma. Ginzburg and colleagues found only 17 cases published over 20 years, probably because many of these patients present with sudden death.1 LAD is the most frequently injured artery (76%) followed by the right coronary (12%) and the circumflex (6%) arteries. The dissection begins with a small intimal tear caused by the combination of sudden compression of the anterior chest wall and shearing forces following the impact.2 Intimal tear evolves under hemodynamic trauma, and disruption of endothelial lining causes coronary thrombosis and myocardial infarction (MI), the most frequent mode of presentation of coronary artery dissection, as in our patient.3 In addition to the young age of the patient, the circumstance of this MI, occurring less than 1 month after a violent trauma, must evoke traumatic etiology. Coronary angiography is the established diagnostic procedure to accurately depict intimal tear or thrombosis, but this invasive technique carries a hypothetical risk of worsening a small proximal dissection through catheter manipulation. In some cases, intravascular ultrasound is reliable in the assessment of the dissection and in making good therapeutic choices.3,4 However, this special procedure, which requires sedation, is also invasive and rarely available. Nowadays, with the growing use of noninvasive imaging techniques, especially 64-slice scanners, the diagnosis of coronary artery dissection has become very easy. MDCT shows coronary artery dissection in the classic form of a dilated artery with 2 parallel lumens, separated by the intimal flap. The true lumen is slightly narrowed by a larger, aneurysmal false one, as in our patient. A complete or partial thrombosis of the false lumen is
Drawbacks of MDCT are the use of ionizing radiations, iodinated contrast material, and the need for regular and slow pulse rate in a conscious and cooperative patient. Some authors advocate conservative management of posttraumatic coronary artery dissection, relying on spontaneous healing of intimal tear. The use of thrombolytic agents may worsen the dissection itself, not to mention the high risk of bleeding from other posttraumatic lesions, and is not systematically recommended. Revascularization through coronary artery bypass is the most frequent treatment found in the literature, especially in the presence of other cardiac lesions, such as valvular disruption, requiring simultaneous surgical repair. Endovascular stenting has been performed many times with good long-term results. With the expected increase of use of MDCT in trauma patients, more coronary artery dissections will be diagnosed, raising the question of whether to stent these asymptomatic patients.

This unique case shows the importance of MDCT as a first-line noninvasive diagnostic tool in suspected posttraumatic coronary lesions.
