

Donor-Derived Keratinocytes in Actinic Keratosis and Squamous Cell Carcinoma in Patients with Kidney Transplant

Journal of Investigative Dermatology (2013) 133, 1108–1111; doi:10.1038/jid.2012.422; published online 29 November 2012

TO THE EDITOR

The homing ability of hematopoietic stem cells has enabled their therapeutic use. We have previously shown in allogeneic hematopoietic stem-cell recipients that donor-derived cells can be detected in skin in acute graft-versus-host disease (Murata *et al.*, 2007) and in squamous cell carcinoma (SCC) of the oral mucosa (Janin *et al.*, 2009). In kidney transplant recipients, population-based studies show an increased risk of skin SCC (Moloney *et al.*, 2006; Wisgerhof *et al.*, 2010), which are remarkable for: (i) their incidence, 250 times higher than in the normal population (Mackenzie *et al.*, 2010), (ii) their prevalence over basal cell carcinoma, (iii) the fact that they are multiple, and (iv) their association with multiple actinic keratosis (AK). Donor-derived cells have been identified in one case of basal cell carcinoma (Aractingi *et al.*, 2005). Here we address the question of the presence of donor-derived cells in skin SCC and in associated AK in kidney transplant recipients.

In three patients with AK and SCC who had received sex-mismatched kidney transplants, and for whom remaining tissue samples and DNA from donor and recipient were available, we conducted a chimerism study using four independent methods, FISH for X and Y chromosome detection, ZFYqPCR, polymorphic microsatellite analyses, and HRM on mitochondrial DNA (Supplementary Data online). The study was approved by the Institutional Review Board of Hôpital Saint-Louis (Paris, France) and written informed consent was obtained according to the Helsinki Declaration.

AK and SCC lesions included in this study were not contiguous, but 5 to 10 cm apart.

XY-FISH combined with cytokeratin on the same tissue section showed cytokeratin-positive cells with the donor genotype in two female recipients of male kidney transplants. The percentage of chimeric cells was 4% in the SCC and 2% in the two AKs studied for Patient 1 (Figure 1a), and 5% in the SCC and 3 and 0% in the two AKs studied for Patient 2 (Table 1). Chimeric XY cells were distributed in the basal layer in AK and in the basal layer and the invasive areas in SCC. No chimeric cell was found in normal surrounding skin. The third patient with sex-mismatched kidney transplant (Patient 3) was male, and no chimeric XX cytokeratin-positive cell was found in his SCC or AK.

As donor-derived cells were only found in female recipients of male kidney transplants, we performed a qPCR for ZFY gene on AK and SCC tissue sections, which confirmed the presence of the Y chromosome in Patient 1 SCC and two AKs (Figure 1b) and Patient 2 SCC and one of the two AKs studied.

To check these chromosomal results using completely different methods, which also associated molecular markers and morphological selection of cell populations, we performed microsatellite PCR and HRM analyses on laser-microdissected cells. Laser microdissection, performed on tissue sections after immunostaining of inflammatory cells, enabled us to collect only keratinocytes from the basal layer in AK and keratinocytes from the basal layer and from invasive areas in the dermis in SCC (Figure 1c). The polymorphic microsatellite marker analyses performed on laser-microdissected cells confirmed the presence of cells of donor origin in the SCC and two AKs of Patient 1, using four different

dinucleotide repeats: D3S3611, D5S2095, D8S1820, and D9S162 (as shown for D3S3611 in Figure 1d). It also confirmed the presence of cells of donor origin in the SCC and one AK of Patient 2, using three different dinucleotide repeats: D3S1597, D5S2095, and D8S1820. Polymorphic microsatellite analyses D3S3611, D8S1820, and D17S1879 showed recipient origin for Patient 3 SCC and AK.

We performed mitochondrial DNA HRM in the same samples of laser-microdissected keratinocytes from AK and SCC. This second independent method also showed the presence of cells of donor origin in the SCC and two AKs of Patient 1 (Figure 1e), and in the SCC and one AK of Patient 2. The cells of the SCC and AK of Patient 3 were all of recipient origin.

Altogether, we provide conclusive evidence for the presence of donor-derived basal keratinocytes in AK, and of donor-derived basal and invasive keratinocytes in skin SCC in two kidney transplant recipients.

These data imply the homing of stem/progenitor cells from the kidney transplants to the recipients' skin. For the homing of stem/progenitor cells from adult kidney to the skin, no experimental data are available. Multipotent progenitor cells from Bowman's capsule in adult human kidney have been isolated and characterized (Sagrinati *et al.*, 2006), but a transfer of mesenchymal stem cells with the transplant cannot be excluded.

Using combined XY-FISH and immunostaining on whole tissue sections enabled us to observe that chimeric cells were only present in SCC and AK, and not in normal peripheral skin. In addition, the donor-derived cells we identified in SCC were located in the basal layer and in invasive areas, which correspond to the "outer proliferating layer" where tumor-initiating cells have recently

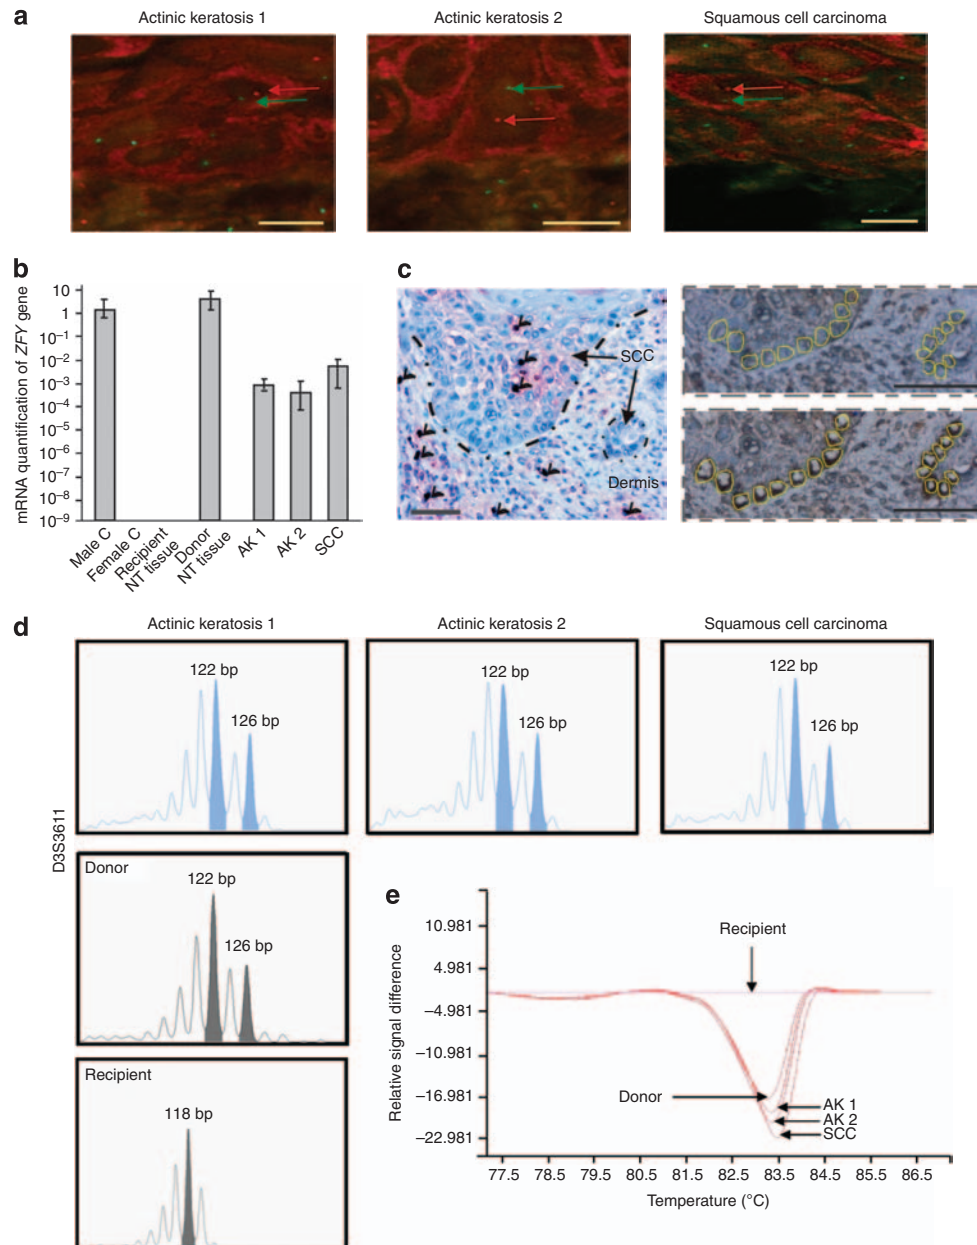

Figure 1. Cells of same donor origin in AK and SCC in Patient 1. (a) Using FISH-XY, cytokeratin-positive basal cells with an X (green) Y (red) genotype are detected in AK and SCC. Scale bars = 10 μ m. (b) PCR detects Y chromosome in the two AKs and SCCs of the female recipient. (c) Laser microdissection of CD45-negative basal and invasive cells in SCC. Arrows: CD45-positive cells. Scale bars = 100 μ m. (d) Comparison of DNA profiles from laser-microdissected keratinocytes from AK and SCC with donor and recipient normal cells. Microsatellite analysis at D3S3611 locus shows donor origin (base-pair 122 and base-pair 126) of the microdissected keratinocytes from the two AKs and the SCCs. (e) Mitochondrial DNA-HRM PCR shows similar profiles for laser-microdissected keratinocytes of the two AKs and SCCs, and for donor cells.

been characterized in skin SCC (Patel *et al.*, 2012). We also identified donor-derived cells in the basal layer of AK, which is usually considered as a benign disease, although molecular studies have shown frequent loss of heterozygosity (Rehman *et al.*, 1994) and gene expression patterns are in favor of a spectrum of disease progression from

normal human skin to AK and SCC (Padilla *et al.*, 2010). In our cases, the concentration of chimeric cells in AK and SCC could be linked to the tissue remodeling accompanying disease progression, as stem/progenitor cells are recruited to the sites of skin injuries in experimental conditions (Zong *et al.*, 2008), and tissue repair shares common

mechanisms with stem-cell renewal in carcinogenesis (Beachy *et al.*, 2004). In the kidney transplant recipients we studied, the precise role of chimeric stem cells in skin SCC oncogenesis remains to be established, but the detection of chimeric cells at the stage of AK is in favor of a multistep process in the disease progression.

Table 1. XY-FISH data in AK and SCC of three sex-mismatched kidney transplant recipients

Recipient/ donor	Sex	Kidney transplantation		Skin tumor		XY FISH

				Leg	AK	0	101	141	0.0	71.6	

¹Tumor samples from two patients with SCC and AK without kidney transplantation setting (control) were examined. To determine the efficiency of sex chromosome detection in basal and suprabasal layers of SCC and AK, a FISH-XY protocol was applied. Tumor sections from the two patients with SCC and AK were analyzed and the percent detection averaged for either SCC $\{((79:127) + (72:112) \times 100) : 2 = 63.25\%$ or AK $\{((102:147) + (101:141) \times 100) : 2 = 70.5\%$. The normalization factor was derived by dividing 100% by the average percent for either SCC (100:63.25 = 1.58) or AK (100:70.5 = 1.42). Here the normalization factor was 1.42 and 1.58 for XX and XY cells detections of AK and SCC, respectively.

Evidence of Differentiation in Myeloid Malignancies Associated Neutrophilic Dermatitis: A Fluorescent *In Situ* Hybridization Study of 14 Patients

Journal of Investigative Dermatology (2013) 133, 1111–1114; doi:10.1038/jid.2012.408; published online 29 November 2012

TO THE EDITOR

Neutrophilic dermatoses (NDs) are characterized by dense infiltrates of mature neutrophils typically located in the upper dermis. Despite having dissimilar clinical presentations, Sweet's syndrome, pyoderma gangrenosum, neutrophilic eccrine hidradenitis, and other related disorders are recognized as part of the spectrum of NDs because of their overlapping clinical and histopathological findings (Vignon-Pennamen and Wallach, 1991). Although most instances of ND have a benign course, some extracutaneous localizations of the neutrophilic infiltrates can be potentially life-threatening (Vignon-Pennamen, 2000).

Little is known about the pathophysiology of ND. The findings of high CD3, IL-1, IL-8, and tumor necrosis factor- α expressions by immunohistochemical staining in the dermis of ND patients (Marzano et al., 2010) and the impressive effects of corticosteroids in alleviating these diseases have underlined a role for activated T lymphocytes in the recruitment of mature neutrophils to the dermis. Moreover, targeted immunosuppressive agents such as tumor necrosis factor- α inhibitors and the IL-1R inhibitor anakinra have been successfully used in the treatment of Sweet's syndrome, which has further emphasized the importance of these cytokines in the pathophysiology of

ND (Yamauchi et al., 2006; Delluc et al., 2008; Lipsker et al., 2010).

Around 20% of patients with Sweet's syndrome have an underlying hematological malignancy, which is predominantly a myeloid neoplasm (Cohen et al., 1988). In these cases, one could hypothesize that neutrophils have differentiated from the malignant clone, showing an aberrant phenotype, which promotes dermal invasion. In this model, neutrophils in the dermal infiltrate should be clonally related to the underlying myeloid malignancy, which has never been formally demonstrated to date.

We thus conducted a multicentric retrospective study, which included 14 ND patients (8 men and 6 women) with (1) a histopathological diagnosis of Sweet's syndrome ($n=12$), pyoderma gangrenosum ($n=1$), or neutrophilic eccrine hidradenitis ($n=1$), and (2) a diagnosis of myelodysplastic syndrome (MDS, $n=2$) or acute myeloid leukemia (AML, $n=12$), and with a medullar cytogenetic abnormality that would be informative in a fluorescent *in situ* hybridization (FISH) study.

In two patients, the ND was present at the initial presentation of AML. This condition was chemotherapy-induced in seven patients and occurred without any identifiable trigger in four patients. All patients but one were febrile when the ND diagnosis was established, and

four patients had an extracutaneous involvement (lung ($n=1$), muscle ($n=1$), mouth ($n=2$)), which is a much higher frequency than what is reported in idiopathic ND (Vignon-Pennamen, 2000). No patient had concomitant neutrophil leukocytosis. Three patients were profoundly neutropenic at the time of ND occurrence. This observation confirms that hyperleukocytosis is irrelevant as a diagnostic criterion for ND associated with myeloid malignancies.

To test the hypothesis of a clonal relationship between the skin-infiltrating neutrophils and the bone marrow blasts, the FISH study was conducted on 3 μ m skin tissue sections processed using the Histology FISH Accessory Kit (Dako, Glostrup, Denmark). After hybridization with specific probes (Table 1), scoring of the hybridization signals was performed on 200 consecutive morphologically intact nuclei, with a normal cutoff value evaluated at 10% (Haralambieva et al., 2002). This approach was noninformative in three patients because of an insufficient number of analyzable nuclei. Among the other 11 patients analyzed, 8 showed the same cytogenetic anomaly in the neutrophils infiltrating the skin and in the bone marrow (Figure 1), whereas there were no evidence of any clonal cytogenetic abnormality in the neutrophils of the remaining three patients.

A previous study using a HUMARA assay has found evidence of clonality in the skin neutrophils of 80% of women (median age 60 years) with ND, regardless of whether they had an underlying

Abbreviation: AML, acute myeloid leukemia; FISH, fluorescent *in situ* hybridization; MDS, myelodysplastic syndrome; ND, neutrophilic dermatosis
