Abstract

SmartTools is a semantic framework generator, based on XML and object technologies. Thanks to a process of automatic generation from specifications, SmartTools makes it possible to quickly develop environments dedicated to domain-specific and programming languages. Some of these specifications (XML, DTD, Schemas, XSLT) are issued from the W3C which is an important source of varied emerging domain-specific languages. SmartTools uses object technologies such as visitor patterns and aspect-oriented programming. It provides code generation adapted to the usage of those technologies to support the development of semantic analyses. In this way, we obtain at minimal cost the design and implementation of a modular development platform which is open, interactive, uniform, and most important prone to evolution.

Key words: software generation, development environment, semantic analyses, aspect-oriented programming, visitor pattern, program transformation, XML, XSLT.

1 Introduction

With new technologies related to data processing for Internet applications, the concept of language is more and more used to structure information. Therefore, the World Wide Web Consortium (W3C) has introduced new formalisms such as DTDs (Data Type Definitions) or Schemas that popularize the concept of abstract syntax, the basic component to manipulate any program. Additionally, the software quality and the development speed are of major concern in this particular application area. That justifies the creation of a software generator strongly based on XML (eXtensible Markup Language) and object technologies, named SmartTools.

The main goal of this software generator is to help designers of domain-specific or programming languages. No more than one specification (e.g. a DTD) is needed
to quickly produce a dedicated development environment. Both the target environment and the SmartTools framework must fulfill the following requirements:

- easy to use with a minimal knowledge and based on well-known techniques or standard specifications,
- modular and flexible implementation based on re-usable and generic components, and on a distributed software architecture,
- user-friendly thanks to a Graphic User Interface (GUI) that offers multi-views and an interactive environment,
- open thanks to a standard data exchange format used to communicate with its components and other external applications.

To ease the development of semantic analyses, several techniques have been introduced into SmartTools. First, the solution of visitor design pattern [9] was largely automated with the generation of Java source code from abstract syntax definitions. Second, the aspect-oriented programming was added to obtain more re-usable semantic components. This new functionality does not require any program transformation. Thus, the addition of aspects on a visitor can be completely dynamic (without recompilation). Section 2 presents these semantic tools.

To meet with the architecture requirements, the modular software architecture was built around a central software component: the message controller. SmartTools is made of several independent software components that communicate with each other by exchanging asynchronous messages. The XML technologies are used to encode these messages. In Section 3, the modular architecture of SmartTools is described.

Concerning the interactive requirements, SmartTools has an extensible and modular GUI with a set of pretty-printers or viewers strongly based on XML technologies. For data integration and to be open to new application fields, the XML format is used for all data exchange between components and as an description language for new applications. These interactive functionalities are presented in Section 4.

About the re-usability requirement, SmartTools uses and provides several advanced software technologies stemming from various research works [2,4,11,12,16,23], but homogeneously gathered together. In fact, web applications and the emergence of XML technologies are assets for a large diffusion and new application fields for this software generator.

2 Semantic Tools

Internally, SmartTools uses extended and strongly typed abstract syntax (AST) definitions for all its tools. The important notions of these definitions are: operators and types. The operators are gathered into named sets: types. The sons of operators are typed and named. Figure 1 shows the definition of our toy language: tiny. For example, the affect operator belongs to the Statement type and has two sons: the

---

1 used all along this article
first one is of type `Var` and the second one of type `Exp`.

```plaintext
Formalism of `tiny` is
Root is `%Top`;
Top = program(Decls declarationList, Statements statements);
Decls = decls(Decl[] declarationList);
Decl = intDecl(Var variable), booleanDecl(Var variable);
Statements = statements(Statement[] statementList);
Statement = affect(Var variable, Exp value),
while(ConditionExp cond, Statements statements),
if(ConditionExp cond, Statements statementsThen,
Statements statementsElse);
ConditionOp = equal(ArithmeticExp left, ArithmeticExp right),
notEqual(ArithmeticExp left, ArithmeticExp right);
ConditionExp = %ConditionOp, true(), false(), var;
ArithmeticOp = plus(ArithmeticExp left, ArithmeticExp right),
minus(ArithmeticExp left, ArithmeticExp right),
mult(ArithmeticExp left, ArithmeticExp right),
div(ArithmeticExp left, ArithmeticExp right);
ArithmeticExp = %ArithmeticOp, int as STRING, var as STRING;
Exp = %ArithmeticOp, %ConditionOp, var, int, true, false;
Var = var;
End

Fig. 1. the AST definition of `tiny`
```

From any AST definition, SmartTools can automatically generate a structured editor specific to the language. To facilitate the editing (to copy-paste nodes), it is useful to make the type inclusion possible.

We want, as much as possible, to use existing software components stemming from the W3C standards, such as the DOM (Document Object Model) API to handle XML documents. But, this latter API does not consider strongly typed structures. To manipulate strongly typed trees, we have extended it with the notions of fixed node, listed node and typed node (c.f. Figure 2). In this way, the tree consistency is guaranteed by the Java type-checker at its construction. For each operator, SmartTools automatically generates one class and the associated interface (Figure 3 shows the interface generated for the `affect` operator), and one interface by type. These classes contain the getters and setters needed to handle the sons (e.g. `getValueNode`, `setValueNode`).

![Fig. 2. Class hierarchy for the affect operator](image)

\(^2\) marked with the % sign in Figure 1
package tiny.ast;
public interface AffectNode extends StatementType {
    public tiny.ast.VarType getVariableNode();
    public void setVariableNode(tiny.ast.VarType tree);
    public tiny.ast.ExpType getValueNode();
    public void setValueNode(tiny.ast.ExpType tree);
}

Fig. 3. Generated affect operator interface: AffectNode

It is important that the language designers can define their languages (abstract syntax) by using standard formats (DTD or Schema) proposed by the W3C and not necessarily with the internal AST definition format of SmartTools. Therefore, we have implemented conversion tools with some restrictions. For example, the notion of type does not explicitly exist within the DTD format i.e. the elements (seen as operators) do not belong to named sets. As this notion was essential, we had to define a type inference mechanism to convert DTDs. Additionally, the right part of element definitions should only contain parameter entity references to indicate the types of the sons (e.g. the line 6 of Figure 4 shows a DTD-equivalent definition of the affect operator). Unfortunately, few DTDs are written in this way. To be able to accept as many DTDs as possible, a more complex type analysis (type inference) was carried out.

Fig. 4. Part of the generated DTD of tiny

Moreover, we have implemented generators that produce a parser and the associated pretty-printer to manipulate programs with a more readable format than the XML one. For this purpose, the designer has to provide extra attributes information on each element (or operator) definition (see attributes in Figure 5). This possibility is useful for designers that do not have expertise on how to write a parser and makes sense only for small and unambiguous languages.

Fig. 5. Extra data of the affect operator useful for generating a parser and the associated pretty-printer

Figure 6 shows all the specifications that can be generated from an AST specification:
- the API of the language (i.e. one class and the associated interface by operator, and one interface by type),
the basic visitors useful for creating semantic analyses,
a parser for the language (if extra syntactic sugars are provided as operator attributes in the language definition),
a pretty-printer to unparse ASTs according to these extra syntactic sugars,
a minimal resource file that contains useful information for the structured editor and the parser,
the DTD or the Schema.

![Diagram of API and specifications generation](image)

Fig. 6. All the specifications generated from an AST

For example, thanks to these tool generators, the tiny environment was automatically generated only from one AST specification (see Figure 1 page 3), one xprofile specification (see Figure 7), and the type-checker visitor (100 Java lines).

### Semantics

This sub-section presents ways to write analyses (e.g. a type-checker, an evaluator or a compiler) on programs by using the visitor design pattern. If the reader wants to have more details and explanations on this well-known methodology, he can refer to [9,21,22]. For instance, we present three extensions of the visitor pattern technique: v1 using reflexivity mechanism with profiled visits and tree traversal possibilities, v2 adding simple aspect-oriented programming, v3 splitting the tree traversal (visit method calls) and the semantic actions by using more complex aspects.

**Reflexive visitors (v1)**

To make the development of visitors based on the AST definitions easier, SmartTools automatically generates two visitor classes: AbstractVisitor and TraversalVisitor. The abstract visitor declares all the visit methods (one by operator). The TraversalVisitor inherits from the AbstractVisitor and implements all the visit methods in order to perform a depth-first tree traversal. This visitor can be extended and its visit methods refined (overridden) to specify an analysis.
Thanks to the xprofile specification language of SmartTools, it is possible to specify the visit signatures i.e. to generate visits with different names, return types, and parameters. The granularity of this personalization is at the (AST) type level. Figure 7 presents the xprofile specification of a type-checker for tiny. From this specification, the system automatically generates the two correctly-typed visitors (AbstractVisitor and TraversalVisitor). Only useful visit methods have to be overridden to implement the type-checker (see Figure 8 for the affect operator). The advantage of using profiled visits is to avoid casts and obtain more readable visitor programs.

```
XProfile TypeChecker;

Object check(%Statement, TinyEnv env);
String check(%Exp, TinyEnv env);
String check(%ArithmeticOp, TinyEnv env);
String check(%ConditionOp, TinyEnv env);
String check(%ArithmeticExp, TinyEnv env);
String check(%ConditionExp, TinyEnv env);
String check(%Var, TinyEnv env);
Strategy TOPDOWN;
```

Fig. 7. Visit signatures of a type-checker for tiny

```
public Object check(AffectNode node, TinyEnv env) throws VisitorException {
    String varName = node.getVariableNode().getValue();
    String typeLeft = env.getType(varName);
    String typeRight = check(node.getValueNode(), env); //visit the value node
    if (typeLeft == null)
        errors.setError(node, "This variable " + varName + " was not declared");
    else {
        if (!typeRight.equals(TinyEnv.ERROR) && (!typeLeft.equals(typeRight)))
            errors.setError(node, "Incompatible types: " + varName + " is a" +
            typeLeft.equals(TinyEnv.INT)?"int":"bool") + " variable");
    }
    return null;
}
```

Fig. 8. Affect visit of the type-checker

With the xprofile language, it is also possible to specify the tree traversal (from the starting node to the destination node(s)) of a visitor. Thus, only the nodes on the path are visited instead of all the nodes of the tree. It reduces the visitor runtime on sizeable trees and above all the size of the generated visitors. A dependence graph analysis on the AST definition is performed to generate the corresponding abstract and traversal visitors with the ‘right’ visits according to the given path. For example with the traversal specified on Figure 9 only the visits of the while and affect operators and the visits of the operators contained between the root (TOP) and these operators (i.e program, statements and if according to the AST definition of Figure 1 page 3) will be called.

In SmartTools, we use the Java reflexivity mechanism to implement the visitor technique and not the classical solution of a specific method, usually denoted
Traversal Test:
\$\text{\textbf{Top}} \rightarrow \text{while, affect};$

Fig. 9. Traversal specification from the root (\textit{TOP}) to \textit{while} and \textit{affect}

accept, defined on each operator\(^3\). Indeed, the introduction of a visitor profile prohibits from using this classical solution (\textit{accept} method). A generic method (named \textit{invokeVisit}) is executed when any visit method is called. The goal of this generic method is to invoke the ‘right’ visit method (with a strongly-typed node) by using reflexivity.

The use of reflexivity is runtime-expensive. To accelerate the invoke process, an indirection table is statically produced at compilation-time when the abstract visitor is generated. This table contains for each pair (operator, type) the Java reference to the visit \texttt{java.lang.reflect.Method} object to call. With this table, it is also possible to change the visit method name and to have different arguments. This solution is a simplification of the multi-method approach that dynamically performs the search of the best method to apply. We have compared these two approaches by using a Java multi-method implementation \cite{8}. The performances are equivalent, but our approach is much easier to realize.

Visitors with Aspect (v2)

The reflexivity mechanism used to implement the visitor pattern technique makes the execution of additional code before or after the visit calls possible. In this way, a concept of aspect-oriented programming \cite{13,15} specific for our visitors can be added without modifying the source code, unlike the first versions of AspectJ \cite{11,14}. An aspect can be defined just by implementing the \texttt{Aspect} interface and then recorded (see methods on Figure 10) on any visitor. For example, if the aspect of Figure 11 is recorded on a visitor, it will trace out all the called visits.

Several aspects can be connected on a visitor. They are executed in sequence (according to the registration order). This connection (as well as the disconnection) can be done at runtime. The behavior of a visitor can thus be modified dynamically by addition or withdrawal of these aspects. For example, a graphical debug mode for the visitors with a step-by-step execution was specified as an aspect regardless

\begin{verbatim}
VisitorImpl
+visit(node:Node, params:Object): Object
#invokeVisit(params:Object[]): Object
+addAspect(aspect:Aspect): void
+removeAspect(aspect:Aspect): void
+addAspectOnOperator(op:Operator, aspect:Aspect): void
+removeAspectOnOperator(op:Operator, aspect:Aspect): void
+addAspectOnType(type:Type, aspect:Aspect): void
+removeAspectOnType(type:Type, aspect:Aspect): void
\end{verbatim}

Fig. 10. Visitor with aspect (v2) API

\(^3\) SmartTools can also help designers to develop this kind of efficient visitors. But, their codes are less readable (more casts, no aspect, no tree traversal choice, etc) than the v1 or v2 visitors. Therefore, we do not describe them in this article.

103
package fr.smarttools.debug;
import fr.smarttools.tree.visitorpattern.Aspect;
import fr.smarttools.tree.Type;

public class TraceAspect implements Aspect {
    public void before(Type t, Object[] param) {
        System.out.println("Start visit on " + param[0].getClass());
    }
    public void after(Type t, Object[] param) {
        System.out.println("End visit on " + param[0].getClass());
    }
}

Fig. 11. Aspect that traces out the visit methods

of any visitor. To add these aspects on the v1 visitors, the generic method (invoke-Visit) was extended.

Visitor with Tree Traversal and complex Aspects (v3)

With the concept of aspect-oriented programming, it is possible to split the tree traversal (visit method calls) and the semantic processing (semantic actions). Let us suppose that the visit code of the affect(Var, Exp) operator has this shape:

```
visit(AffectNode node ...) {
    codeBefore
    visit of the first son
    codeBetween1_2
    visit of the second son
    codeAfter
}
```

One can observe that the semantic part (i.e all except the recursive calls) is divided into N sons + 1 pieces of code. These N+1 pieces can be treated like aspects with new points of anchoring, i.e before, between and after the visit method calls of the sons. We have defined a new visitor (named v3 visitor) that takes as arguments a tree traversal and one or more semantic actions (i.e. in the form of aspects) as shown on Figure 12. This visitor can call these aspects on these new points of anchoring. Therefore, these aspects must have for each operator, in addition to the traditional before and after methods, the between_i_i+1 methods (code to be executed between the i\textsuperscript{th} and i+1\textsuperscript{th} sons). This new visitor can connect one or more aspects described in the v2 visitors. Figure 13 shows the type-checker semantics associated with the affect operator using this new form of aspect. There is no more recursive call unlike the v1 (see Figure 8 page 6 line 4) or v2 visitors but it is necessary to use stacks (see Figure 13 lines 5 and 6) to transmit the visit results of the sons.

The type-checker of tiny was extended with an initialization check on variables (see Figure 14) only by composing the two aspects (see Figure 15). The main interest of this programming style is to make the extension of analyses possible without modification only by adding new aspects. In this way, analyses are modular and re-usable. However, these analyses are more complex to program because of the splitting of the semantics and the tree traversal (compare Figures 13 and 8 page 6). Currently, we study how to share data between semantics, problems linked to the common tree traversal (e.g. what to do if one semantics wants to loop on a node and not the others?) ; we also study mechanisms to ease the programming of these
For the v3 visitor (see Figure 12), there is also a generic method that manages the next node to visit according to the current position, the tree traversal and some special traversal instructions. This method also copes with the search of the next method to call and the invocation of the v2 aspects on these visits.
3 Architecture

SmartTools is composed of independent software modules that communicate with each other by exchanging asynchronous messages. These messages are typed and can be considered as events. Each module registers itself on a central software component, the message controller (c.f. Figure 16), to listen to some specific types of messages. It can react to them by possibly posting new messages. The controller is responsible for managing the flow of messages and delivering them to their specific destination(s). The components of SmartTools are thus event-driven. This section presents the different modules of SmartTools and describes the behavior of the message controller.

The main software modules of SmartTools are the following:

- Each **document** contains an AST. In Figure 16, **Document 1** and **Document 2** contain the ASTs on which the user is working. **Document GI** is a special one. It contains the AST describing the structure of the GUI (e.g. the AST of the Figure 23 page 15).

- The **user interface** module manages the views, the menus and the toolbar of SmartTools.

- Each **view** is an independent module showing the content of a document in a format depending on the type of the view. For example, some views display the tree in colored-syntax text format, others as a graphical representation.

- The **parser manager** chooses the right parser to use for a file. Then, it runs the parser and builds the corresponding AST. The **document manager** uses this tree to build a document module and connects it to the message controller.

- The **base** is a module that contains definitions of resources used in SmartTools: colors, styles, fonts, menus, toolbars, actions, etc.

Of course, new types of modules can register themselves on the message controller. That is one of the ways to extend the features of SmartTools for a specific purpose or to embed SmartTools in another environment.

When a module needs to communicate with another module, it creates a message and posts it on the message controller. Then, the message controller broadcasts this message to the appropriate listeners (modules) that will react to it. Thus, mod-
ules that want to receive special types of messages from the message controller have to become listeners of these types of messages. They have to implement the `MsgListener` interface and provide a `receive(xxxMsg)` method for every type of supported message. Then, they have to register on the message controller (see code just below) and obtain their unique module identifier from it.

```java
idDoc = msgController.register(this);
```

`XxxMsg` in the `receive` method stands for the class of the expected message. Messages are typed objects i.e there is one specific class for every type of message. Their common behavior is held in one abstract class that is the super class of all the messages. New kinds of messages can be created by extending that common class or any other existing message class.

In the following example, the module expects to receive `SelectMsg`, `CloseDocMsg` and `CutMsg` messages sent to the module identified by `idDoc` and coming from an anonymous sender.

```java
msgController.addMsgListener("SelectMsg", idDoc, Msg.ANONYMOUS);
msgController.addMsgListener("CloseDocMsg", idDoc, Msg.ANONYMOUS);
msgController.addMsgListener("CutMsg", idDoc, Msg.ANONYMOUS);
```

Documents (i.e ASTs) and views are independently registered on the message controller. A document does not need to know how many views are related to it. When a modification is made, the document posts a modification message. The type of that message indicates which modification has been done and the message body contains the path of the modified node (from the root of the tree). For some kinds of messages, the change is also specified. Such messages will be sent only to the views that are registered to receive these modification messages coming from this document. Other modules will not receive them.

The message controller has a built-in message filtering capability. It is possible to write filters that watch or influence the flow of input and output messages on the controller. That filtering capability has been successfully used for several specific needs: benchmarking, debugging, undoing user actions, and automatically translating messages into another format (SOAP messages).

The architecture of SmartTools is designed to ease connection with other development environments or tools. Some experiments [24] are in progress to provide several features of SmartTools as Web services and to use them from a client tool running on a .NET platform.

### 4 Graphical User Interface

SmartTools has a GUI (c.f Figure [17]) based on the document/views concept i.e. the user interface is the framework in which views on a document (AST) can be displayed and manipulated. For each open document, it is possible to build and display one or more views showing different aspects of the tree according to different formats. XML technologies are extensively used to build this GUI and the different views.

A view on a document is built by applying a transformation to its AST. We
have experimented with two different approaches to perform tree transformations and build graphical views. The first approach was to write a visitor that transforms the tree and directly builds the hierarchy of graphical components. That was fast and efficient but required to recompile every time a change was done in the transformation. The second technique was to specify a tree transformation using XSLT to produce a BML (Bean Markup Language) description of graphical components to create. The BML result is then interpreted (see Figure 18) to build the actual view. Even though there is a loss of efficiency when using XSLT and BML engines, the technique has proved to be easier to learn, more open to new view designs, and well-adapted for sending views through networks.

Xpp language

A higher-level transformation language, called Xpp, has been defined on top of XSLT to specify the pretty-printing of XML documents. Its features are similar to those of XSLT but it is much more concise, more readable and it can perform transformations only on subtrees for incremental purposes. Xpp consists of a set of rule definitions (see Figure 19) which match patterns with explicit variables for subtrees. These variables are used in the right part for recursive calls.

We have defined formatting functions (horizontal or vertical alignment, indentation, etc.) that designers may use to write their pretty-printers in the right part of the rules. When Xpp specifications are translated into XSLT stylesheets (see Figure 20), the designers only need to indicate the expected output format (either BML, HTML or text at the moment) useful for the system to choose the right implementation of the formatting functions (see Figure 21).

The $\text{plus}(x,y) \rightarrow h(x, \text{label}("+"), y)$; Xpp rule specifies that the
left and right subtrees for each \texttt{plus} operator will be horizontally aligned and separated by the + sign. The \texttt{h} and \texttt{label} formatting functions are defined in all the available output formats. \texttt{Xpp} can be extended by adding new formatting functions defined for every available output format.
Mapping between logical and graphical views

For BML output, every transformation rule specifies how to build a hierarchy of graphical components. Some of these components are associated with nodes of the tree and are marked so. Others are only syntactic sugars and are just ordinary graphical objects (not marked). This marking technique is a convenient way to be able to match any graphical object with its corresponding node in the document tree. When a part of the document tree is modified, an update message is sent to the views of that document. The update message contains the path of the modified subtree and the new subtree. Transformation rules are applied to that new subtree to create a local hierarchy of graphical components: a graphical subtree. The path contained in the update message is interpreted thanks to the marked components and the obsolete graphical subtree is found. It is then replaced by the new one to reflect the document tree modification.

The Base module

Definitions of style (fonts, colors, etc.) are stored in separate XML resource files that are managed by the Base module. When a view (or any other module) needs style information, the Base module uses visitors to find appropriate information in the resources (represented as ASTs). There are three successive search levels: first on a general resource tree, then on the current language-specific resource tree, and finally on the active view-specific resource tree. At every step, the result is overloaded by the newly found information.

GUI description language

A special XML language of SmartTools, called lmltree, was designed to describe the structure of the user interface. From such a description, SmartTools builds its user interface by transforming this description with the XSLT engine. The GUI is thus only a view of this description. Figure 22 shows such a description, Figure 23 the schematic graph of its AST, and Figure 17(page 12) the resulting GUI.
5 Applications

SmartTools has been used to develop or quickly prototype various environments of several domain-specific languages. Its first applications were dedicated to the languages used by the system itself; it is bootstrapped. For instance, specific environments were created to edit the resources, to manipulate AST definitions or visit method profiles. Much more complex and powerful environments can be created with additional work.

An integrated environment for Java \footnote{Its parser was not generated as the Java language is complex} was developed. Figure 24 displays a source file (.java) and its associated class file (.class) on different formats (i.e. using different pretty-printers) as shown on Figure 25. These two documents are linked, thus the selection in one document is communicated to the other. The main tools of this environment are a bytecode type-checker and a bytecode simulator. All these tools use the visitor pattern technique and can be dynamically extended (e.g. with tracing or debugging features) simply by connecting aspects.
As the SmartTools architecture was designed to easily plug new components, servlets can quickly be registered on the message controller. In this way, we have experimented with a distributed version of SmartTools to edit programs on any applet-compatible Web browser thanks to a Java applet. This applet was designed to visualize components expressed in BML and to handle user interactions. It uses the HTTP protocol to communicate with SmartTools through a servlet. A generalization of this experiment (Figure 26) was also performed using Web Services (i.e. units providing data and services to other applications). In this manner, applications can access to these Web services via standard Web protocols and data formats (e.g. XML, SOAP) without worrying about how the service is implemented.

6 Related Work

There are many equivalent or comparable systems [2,4,12,16]. The main difference is that SmartTools strongly uses XML and object-oriented technologies. In this way, our system is open and can take advantage of any further development made around Java and XML technologies. It harmoniously integrates different tools and techniques (e.g. visitor design pattern, aspect) thanks to its modular architecture and has generic visualization tools.

Our visitor approach is strongly based on this research work [21] and very close to other developments [10,17,19]. We essentially use a simplified version of the multi-methods [8,20] instead of using accept methods. In this way, it is possible:
to obtain much more readable visitor programs (i.e. without cast) thanks to the `xprofile` specifications,

- to get a simple kind of adaptative programming thanks to the tree traversal specification,

- to introduce an aspect-oriented programming on the top of the visitor design pattern. Our approach is comparable with a more general one. In SmartTools, aspects can be dynamically connected to visitors and no transformation is needed unlike.

For the modular architecture, we designed a message controller similar to the Toolbus but it is restricted to our needs. That was quite an easy and straightforward solution. We plan to study component technologies (such as EJB, CORBA, Web Services, ObjectWeb etc.) to improve the flexibility of the next architecture version. For data integration, we use XML and for control integration a multicasting approach. With a minimal development effort, using existing software components (RMI API) or standard protocols (SOAP protocol), we have obtained a system where it is easy to:

- plug in new components,

- build a distributed environment in connection with a Web browser or the .NET platform,

- transform it into a distributed version using ProActive.

For interactive requirements, our approach is different as we use XML technologies. Moreover, we apply the same transformation model for the document as well as for the GUI; that is quite an original way of building GUIs. This approach makes the export of views possible through the networks (thanks to XML.

---

5 The Toolbus uses more sophisticated notions: `ATerms` to handle trees and a coordination language to connect components.

6 The terms `data integration` and `control integration` are explained in [3]
The usage of W3C specifications as a source format to generate tools is a great asset for SmartTools. Languages designers and end-users can directly take advantage of the non-proprietary formats provided but also use other W3C technologies inside SmartTools. In a Web application context, this property is important for applications interoperability.

7 Conclusions

We have presented a software generator which produces programming environments strongly based on XML and object-oriented technologies. The most important contribution of this approach is to propose at the same time and with a uniform way, a set of advanced programming features, integrated into a modular architecture, with extensible graphical viewing engines and open to XML. We have chosen to use non-proprietary APIs to be open and to take advantage of future or external developments around W3C specifications. On the semantic level, we present a dedicated aspect-oriented programming approach associated with the visitor design pattern compliant with the DOM specifications. We expect a large set of domain-specific languages to be based on the W3C specifications. The users (and designers) of such languages are not supposed to be experts of language theories. Therefore, we propose a semantic framework easy to use and requiring a minimal knowledge. Domain-specific languages represent a large potential of applications in various fields and will certainly introduce new open problems.
