Duchenne muscular dystrophy is a lethal X-linked muscle disorder. We have already reported that osteopontin (OPN), an inflammatory cytokine and myogenic factor, is expressed in the early dystrophic phase in canine X-linked muscular dystrophy in Japan, a dystrophic dog model. To further explore the possibility of OPN as a new biomarker for disease activity in Duchenne muscular dystrophy, we monitored serum OPN levels in dystrophic and wild-type dogs at different ages and compared the levels to other serum markers, such as serum creatine kinase, matrix metalloproteinase-9, and tissue inhibitor of metalloproteinase-1. Serum OPN levels in the dystrophic dogs were significantly elevated compared with those in wild-type dogs before and 1 hour after a cesarean section birth and at the age of 3 months. The serum OPN level was significantly correlated with the phenotypic severity of dystrophic dogs at the period corresponding to the onset of muscle weakness, whereas other serum markers including creatine kinase were not. Immunohistologically, OPN was up-regulated in infiltrating macrophages and developing myosin heavy chain-positive regenerating muscle fibers in the dystrophic dogs, whereas serum OPN was highly elevated. OPN expression was also observed during the synergic muscle regeneration process induced by cardiotoxin injection. In conclusion, OPN is a promising biomarker for muscle regeneration in dystrophic dogs and can be applicable to boys with Duchenne muscular dystrophy. (Am J Pathol 2016, 186: 1302–1312; http://dx.doi.org/10.1016/j.ajpath.2016.01.002)

Duchenne muscular dystrophy (DMD) is an X-linked disorder of muscle characterized by primary muscle atrophy.1 Its prevalence in the population is estimated to be 1 in 3500 male newborns.2 A DMD gene mutation results in the absence of dystrophin, a structural protein in muscle fibers, leading to fragility of muscles fibers to contractive force.3 Histologic features of DMD are muscle fiber degeneration with secondary cellular inflammation, ineffective muscle fiber regeneration, and eventually fibrosis and adiposis. Hence, patients with DMD have muscle weakness, leading to loss of ambulation and early death from respiratory or cardiac failure.

Clinical biomarkers are necessary for the diagnosis of the disease, classification of the severity, and evaluation of therapeutic effects. Serum creatine kinase (CK) is a primary biomarker for the sensitive diagnosis of DMD, reflecting muscle damage.4 However, serum CK is not sufficient for the evaluation of therapeutic effects because its levels decrease with the progression of dystrophic disease corresponding to skeletal muscle waste. Osteopontin (OPN) is a potential new candidate for development of a method for evaluation of dystrophic conditions. OPN is a

phosphorylated glycoprotein that is synthesized in a variety of tissues and cells, and participates in inflammation, tissue remodeling, and tumorigenesis. The secreted form of OPN, both as a soluble molecule with cytokine functions and as an immobilized matricellular protein, can interact with CD44 and a variety of integrins to activate intracellular signaling pathways and mediate cell-cell and cell-matrix interactions.5,7 The effects of binding of OPN to target cells, including promotion of attachment, proliferation, migration, and chemotaxis of cells, are modulated through cleavage by thrombin and matrix metalloproteinase (MMP)-3, -7, and -12.8,9 In injured or dystrophic muscles, OPN is reportedly expressed in immune cells, myoblasts, and damaged or regenerating muscle fibers, indicating its functional involvement in cellular inflammation, muscle regeneration, and fibrosis.10–16 Serum OPN level elevation is also observed in X-linked muscular dystrophy (mdx) mice.17 OPN may influence the severity of disease in patients with DMD because single-nucleotide polymorphisms in human SPP1 (OPN) correlate with the results of clinical trials.18–19 In our previous study using a dystrophin-deficient dog model, canine X-linked muscular dystrophy in Japan (CXMD3j), we found that OPN is implicated in dystrophic diaphragms at birth before initial respiration, suggesting the participation of OPN in a dystrophic muscle environment even at an early phase.20

In a recent study of other serum biomarkers for which the biological function may be related to that of OPN, MMP-9 and its endogenous inhibitor, tissue inhibitor of metalloproteinase (TIMP)-1, are strongly suggested to be DMD biomarkers.21 MMP-9 is a proteolytic enzyme that degrades extracellular matrix components and is prominently involved in the inflammatory process during muscle degeneration.22–24 TIMP-1 possesses biological properties independent of MMP inhibitory activity, including stimulation of cell proliferation and antiapoptosis.25,26 Elevation of serum MMP-9 and TIMP-1 levels is associated with dystrophic disease, and MMP-9 levels correlate with clinical nonambulation of patients with DMD.21

We hypothesized that OPN is uniquely expressed at the early dystrophic phase, and could therefore be a new biomarker of DMD. However, what the serum OPN level indicates in dystrophic disease is still unclear because its elevation is not constantly observed during disease progression.13,21 In the present study, we analyzed serum OPN levels in CXMD3j dystrophic dogs and wild-type (WT) controls at birth and during growth periods and compared them with levels of serum CK, MMP-9, and TIMP-1. We report here for the first time that the serum OPN level in dystrophic dogs was significantly higher than in WT at birth and in the active muscle regeneration phase. OPN was expressed in infiltrating immune cells and regenerating muscle fibers in dystrophic muscles, suggesting an association with elevated serum OPN levels.

Materials and Methods

Animals

A CXMD3j dog colony was established by insemination of beagles with the sperm of golden retriever muscular dystrophy (GRMD) dogs.27 CXMD3j dystrophic dogs lack dystrophin in the muscle tissue and have dystrophic phenotypes, as observed in GRMD and in human DMD.28 All the animals were cared for and treated in accordance with the guidelines provided by the Ethics Committee for the Treatment of Laboratory Medium-sized Animals of the National Institute of Neuroscience. Forty-nine CXMD3j dystrophic and 40 WT littermates in the second to seventh generations from the first artificial insemination were used in this study. All the serum and muscle samples in this study were routinely taken from the dystrophic and WT dogs raised between September 2002 and September 2014 except the ones used for other interventional studies. Anesthesia in the dystrophic and WT dogs was induced by intravenous injection of 20 mg/kg of thiopental sodium (Ravonal, Mitsubishi Tanabe Pharma, Osaka, Japan) and maintained by inhalation of isoflurane (Isoflur, DS Pharma Animal Health Co., Osaka, Japan). Euthanization was conducted by exsanguination under the anesthetic condition.

Serum Collection and Serum Chemistry

Blood samples were collected from each dog at birth, at the age of 3 and 6 weeks, at 2, 3, 6, and 9 months, and at 1 and 2 years. Umbilical cord blood was obtained after fetuses were expelled with a cesarean section, and blood was withdrawn from all the neonates 1 hour after the initial respiration.20 Each blood sample was treated and assayed for serum CK activity using an automated colorimetric analyzer (FDC3500, Fuji Film Medical Co. Ltd., Tokyo, Japan), as previously reported.29

Enzyme-Linked Immunosorbent Assay Analysis

Serum OPN, MMP-9, and TIMP-1 levels were determined using an enzyme-linked immunoassay (ELISA) kit (USCN Life Science Inc., Wuhan, China) for Canis familiaris OPN (E90899Ca), MMP-9 (E90553Ca), and TIMP-1 (E90552Ca). Sample application was performed in duplicate according to the manufacturer’s instructions. Optical density values of standards and samples were spectrophotometrically measured at a wavelength of 450 nm using a microplate reader (Appliskan, Thermo Fisher Scientific, Waltham, MA). When the values were below the detection limit, they were assigned a value of zero.

Clinical Manifestations

Clinical evaluation of dystrophic dogs as described in our previous reports28–30 was performed with revision of some of the items. Briefly, we evaluated gait and mobility disturbances, limb and temporal muscle atrophy, drooling, macroglossia,
dysphagia, and abnormal sitting posture as clinical signs. The severity of each sign was classified into scores of 1 to 5 (grade 1, none; grade 5, severe) according to a grading scale for CXMD1 (Supplemental Table S1). We used the grading records between October 2007 and May 2013.

Histopathology and Immunohistochemistry

The diaphragm and tibialis cranialis (TC) muscle tissues were sampled by autopsy, as previously described. Briefly, muscle tissues were snap-frozen in cooled isopentane and stored at −80°C before use. Cryostat sections (8 μm) were serially prepared and routinely stained with hematoxylin and eosin.

Immunostaining was performed on serial sections, as previously described. Briefly, all sections were fixed in cooled acetone and blocked with Block Ace (Dainippon Sumitomo Pharma Co., Ltd., Osaka, Japan). Subsequently, the specimens were labeled with primary rabbit polyclonal antibodies to OPN (dilution, 1:100) (RB-9097, Thermo Fisher Scientific), MMP-9 (dilution, 1:1000) (ab38898, Abcam, Cambridge, UK), or TIMP-1 (dilution, 1:200) (AB770, EMD Millipore Corp., Temecula, CA) and with mouse monoclonal antibodies to developmental myosin heavy chain (dMyHC) (dilution, 1:40) (NCL-MHCd, Leica Biosystems, Newcastle, UK), CD11b (dilution, 1:50) (MCA1774GA, AbD Serotec), CD18 (dilution, 1:10) (MCA1780, AbD Serotec), CD68 (dilution, 1:100) (MCA1815T, AbD Serotec), or CD206 (dilution, 1:50) (MCA2519GA, AbD Serotec). Secondary antibodies used were fluorescein-conjugated goat anti-rabbit or anti-mouse IgG (Alexa Fluor 488 or 568, respectively; dilution, 1:1000; Life Technologies, Carlsbad, CA). All sections were treated with 3% hydrogen peroxide to block endogenous peroxidase activity.

mounted with fluorescent mounting medium containing DAPI (Vectashield, Vector Laboratories Inc., Burlingame, CA). Images were captured with a fluorescence microscope BZ-9000 (Keyence, Osaka, Japan) under identical conditions.

Muscle Fiber Counting

All fluorescent images were analyzed with a computer-aided image analysis system (BZ-II Analyzer 1.41, Keyence). Muscle fiber counting was performed to compare the population of OPN- and/or dMyHC-positive muscle fibers. In the dystrophic diaphragm and TC muscle tissues, OPN- and/or dMyHC-positive muscle fibers were counted after removal of weakly positive fibers and were compared at the age of 2 to 4 weeks, 3 to 5 months, and 1 and 2 to 4 years. In each section, four random fields (in original magnification ×20) were selected per specimen. OPN- and dMyHC-positive or -negative fibers in these fields were manually captured, and the number was measured. The total number of muscle fibers was measured with bright images in which we were able to capture fiber outlines. The percentage of positive muscle fibers was calculated as follows:

Total Number of Positive Muscle Fibers/Total Number of Muscle Fibers × 100 (Total Numbers Were Summed From Four Fields).

Cardiotoxin Injection

Nine WT dogs at the age of 3 to 4.5 months were anesthetized and injected with cardiotoxin (a venom from Naja mossambica mossambica, 50 μmol/L, 0.21 mL/kg) (C9759, Sigma-Aldrich,

Figure 2 Osteopontin (OPN) expression in infiltrating macrophages of dystrophic muscles at birth. Serial sections of wild-type (WT) and dystrophic diaphragm and tibialis cranialis (TC) muscles before (A) and after (B) initial respiration are stained with hematoxylin and eosin (H&E) or immunostained for OPN (green) and CD11b (red). Merged immunostained images co-stained with DAPI (blue; nucleus) are also shown. Scale bar = 40 μm.
St. Louis, MO) into the bilateral TC muscles to induce muscle injury and subsequent regeneration. For analgesia treatment, 0.02 mg/kg of buprenorphine hydrochloride (Lepetan, Otsuka Pharmaceutical, Tokyo, Japan) was injected i.m. before the dogs awoke from general anesthesia. Blood samples were collected before injection and 1, 3, 5, and 7 days after injection. Three dogs were euthanized and the bilateral TC muscles removed at 3, 5, and 7 days after injection, respectively. Serum CK and OPN measurement and immunohistological analysis were performed as described above.

### Statistical Analysis

For analysis of serum before and after birth, biomarker levels were compared with a paired *t*-test, and those between WT and dystrophic dogs were compared with an unpaired *t*-test. For serum level analyses at different ages, the Holm multiple test[^32,33] was applied in multiple comparisons between WT and dystrophic levels at all age points. In addition, serum biomarker levels at each age point were compared with the prebirth level with Dunnett’s test. For analysis of cardiotoxin injection, serum biomarker levels on each postinjection day were compared with the preinjection level in the same animals using a paired *t*-test, and the Holm multiple test was used at all postinjection days. For analysis of the percentage of immunopositive muscle fibers, the percentages of OPN- and/or dMyHC-positive muscle fibers in each age range were calculated, and the median values were compared to those at the age of 2 to 4 years using the Mann-Whitney *U* test with

**Figure 3** Osteopontin (OPN) expression in dystrophic muscles at the age of 3 weeks, 3.5 months, and 1 and 2 years. Serial sections of diaphragm and tibialis cranialis (TC) muscles of wild-type (WT) and dystrophic dogs are stained with hematoxylin and eosin (H&E) and immunostained for OPN (green). Muscles from dogs at the age of 3 weeks, 3.5 months, and 1 and 2 years were stained. Scale bar = 100 μm.
Bonferroni correction. Pearson’s correlation was used for correlation studies. The statistical significance level was set at 5%. In the Holm multiple test, the tests were ordered from those with the smallest P value to the largest P value. The test with the lowest probability was then tested first, followed by Bonferroni correction for all tests. The second test was tested with Bonferroni correction involving one less test and so on for the remaining tests. All data are given as the means ± SEM, unless otherwise noted. All calculations were performed with StatView-J software version 5.0 (SAS Institute Inc., Cary, NC).

Results

Analyses of Serum OPN and CK Levels in Dystrophic Dogs at Birth

Serum OPN and CK levels in CXMD1 dystrophic and WT littermates were analyzed using cord blood samples before and 1 hour after birth in a parametric manner (Figure 1A). Serum OPN levels in dystrophic dogs were significantly higher both before and after birth than those of WT dogs. Serum OPN levels were not significantly different between before and after birth in either WT or dystrophic dogs. On the other hand, serum CK levels in dystrophic dogs were significantly higher before and after birth than those of WT, and the postbirth level was drastically increased compared with before birth.

Analyses of Serum Biomarker Levels in Dystrophic Dogs during Growth Periods

Serum OPN, CK, MMP-9, and TIMP-1 levels were examined at different ages during growth periods in a nonparametric manner (Figure 1B). Serum OPN levels in dystrophic dogs were significantly higher than those in WT before and 1 hour after birth and at the age of 3 months. The serum OPN level at the age of 3 weeks remained higher but was not statistically significant compared with that of WT.

Serum CK levels in dystrophic dogs were significantly higher than those in WT at all age points (Figure 1B). The serum CK level in dystrophic dogs transiently decreased at the age of 3 weeks and then progressively increased again until the age of 3 months.

Serum MMP-9 levels in dystrophic dogs were significantly higher at 1 hour after birth and the age of 3 months than those in WT (Figure 1B). The serum MMP-9 level was significantly increased at 1 hour after birth but was then decreased at the age of 3 weeks compared with the prebirth value. Serum TIMP-1 levels in dystrophic dogs were not significantly different compared with those in WT dogs at any of the age points (Figure 1B). The TIMP-1 levels were slightly increased before and 1 hour after birth and at the age of 3 weeks compared with those of WT dogs.

Analyses of Serum Biomarker Levels and Phenotypic Severity in Dystrophic Dogs

We analyzed whether serum biomarkers, including OPN, were correlated with phenotypic severity in dystrophic dogs. For classification of phenotypic variation, clinical manifestations were investigated in dystrophic dogs at the age of 2 months, when they had onset of clinical signs. We found a significant correlation between the total grading score and the serum OPN level, whereas no correlation was found between the score and other markers, including serum CK (Table 1).
Expression in the Diaphragm and Limb Muscle at Birth

We next performed immunostaining to observe OPN expression in WT and dystrophic muscle tissues around birth (Figure 2) because the serum OPN levels in dystrophic dogs revealed a distinct elevation pattern compared with serum CK. Histologic analysis of WT muscles revealed no impairment in muscle fibers at birth and after initial respiration. In the dystrophic diaphragms, we found a sporadic appearance of opaque muscle fibers before respiration (Figure 2A), whereas massive degenerative fibers were noted after respiration (Figure 2B), as previously reported. OPN expression was observed in infiltrating mononuclear cells, which were mostly CD11b-positive immune cells, including macrophages (Figure 2, A and B). Diffuse positive OPN staining was also observed in some interstitial cells and in small muscle fibers in WT and dystrophic muscles.

Histologic examination of TC muscles of dystrophic dogs revealed some opaque fibers both before and after respiration (Figure 2, A and B). In these dystrophic TC muscles, OPN was also expressed in CD11b-positive immune cells and in small-sized muscle fibers.

Diaphragmatic and Limb Muscle OPN Expression at Different Ages

We then examined the pathologic process in dystrophic muscles at different ages (Figure 3). No pathologic findings were observed in any of the WT muscles, and OPN was only detected in some interstitial cells. In the dystrophic diaphragms, degenerative muscle fibers accompanying infiltration of mononuclear cells were often observed at 3 weeks, 3.5 months, and 1 year of age. OPN was expressed in infiltrating CD11b- and CD18-positive macrophages or granulocytes but not CD3-positive T lymphocytes (Supplemental Figure S1). OPN-positive cells were partly co-localized with CD68-positive M1 and CD206-positive M2 macrophages. OPN was intensely stained in a subset of muscle fibers (Figure 3), suggesting regenerating muscle fibers. These OPN-positive fibers were frequently co-stained with dMyHC, an immature and...
regenerating muscle fiber marker (Figure 4A). In these fibers, OPN was strongly expressed in the cytoplasm (Supplemental Figure S2). The histopathologic examination at the age of 2 years revealed fibrosis (Figure 3), and OPN was only faintly expressed in dMyHC-positive muscle fibers (Figure 3 and Figure 4A). In the dystrophic TC muscles, OPN was also expressed in infiltrating mononuclear cells and a subset of muscle fibers (Figure 3). OPN-positive fibers were co-stained with dMyHC, as observed in the dystrophic diaphragm (Figure 4B).

To examine the proportion of OPN-positive immature and regenerating muscle fibers, we analyzed the percentage of OPN- and/or dMyHC-positive muscle fibers at different ages (Supplemental Figure S3). The percentages at each age range were not significantly different compared with that at the age of 2 to 4 years because of the small sample size. In the dystrophic diaphragm, the percentage of OPN and dMyHC double-positive fibers tended to be high at the age of 2 to 4 weeks, 3 to 5 months, and 1 year compared with that at the age of 2 to 4 years, whereas in the dystrophic TC muscle, the value tended to be highest at the age of 3 to 5 months.

**OPN Expression after Cardiotoxin Injection**

We analyzed OPN expression during muscle injury induced by cardiotoxin injection and subsequent regeneration in WT dogs (Figure 5). In the injured TC muscle tissues, mononuclear cells notably infiltrated in necrotic and edematous areas at 3 days after injection. Regenerating muscle fibers expressing dMyHC were increased at 5 and 7 days after injection (Figure 5A). Similar histologic features were observed in three WT dogs euthanized at each postinjection day. OPN was markedly expressed in CD11b-positive mononuclear cells and dMyHC-positive regenerating muscle fibers (Figure 5, A and B), indicating an association with muscle regeneration, as observed in dystrophic dogs. During muscle regeneration, serum OPN tended to increase, but no significant differences were seen at 3, 5, or 7 days after injection (Figure 5C). Serum CK elevation was observed at 1 day after injection, when substantial muscle injury was present.
Comparison of Tissue MMP-9 and TIMP-1 Expression with OPN Expression

Different patterns of elevation were seen between serum MMP-9 and TIMP-1 levels in dystrophic dogs compared with serum OPN and CK. Thus, we performed immunostaining to detect these factors in dystrophic muscles (Figure 6 and Supplemental Figure S4). MMP-9 and TIMP-1 expression was observed in both the dystrophic diaphragm and TC muscles at the age of 3.5 months. MMP-9 was strongly expressed in infiltrating mononuclear cells, which were mainly CD11b- and CD18-positive macrophages or granulocytes (Supplemental Figure S4), and was not detected in dMyHC-positive muscle fibers (Figure 6). TIMP-1 was expressed in CD11b- and CD18-positive mononuclear cells and in dMyHC-positive regenerating muscle fibers. At the age of 2 years, the expression of MMP-9 and TIMP-1 was observed only in some interstitial cells (data not shown).

Discussion

We report that the serum OPN level in dystrophic dogs is elevated and reveals a different pattern compared with serum CK and MMP-9 levels and that this elevation pattern is related to muscle regeneration. Recently, OPN has been considered to be not only an inflammatory cytokine that functions in cellular adhesion and chemotaxis of immune cells, including macrophages, but also a myogenic factor that promotes myoblast migration, proliferation, and fusion into myotubes. Our results suggest that serum OPN can be a new biomarker of DMD that indicates muscle regeneration.

OPN was expressed in immune cells and a subset of regenerating muscle fibers of the dystrophic dog muscles, and a similar phenotype is also observed in patients with DMD. OPN is expressed in macrophages, fibroblasts, myoblasts, and myotubes during the muscle regeneration process after injury by intramuscular injection of snake venom. The up-regulation of OPN expression (6 to 48 hours and 3 to 14 days after venom) is correlated with two distinct phases that consist of the inflammatory response and muscle regeneration. These observations strongly suggest that OPN is an important mediator of muscle regeneration in the early phase. We also observed a higher percentage of OPN-positive regenerating muscle fibers for a longer period in the dystrophic diaphragm, where muscle regeneration is very active, compared with analysis of dystrophic TC muscles. Previous findings in our laboratory revealed that regenerating muscle fibers expressing slow-type myosin heavy chain are increased after the age of 4 months in the dystrophic dog diaphragm, whereas fast-type myosin heavy chain is predominant in the TC muscles. We speculate that OPN may be more closely related to slow-type muscle fibers than fast-type fibers during muscle fiber maturation, although further study is necessary.

In the present study, the serum OPN level in dystrophic dogs was elevated and revealed a different pattern compared with that of serum CK, an established primary biomarker of DMD that indicates muscle injury. The serum CK level in dystrophic dogs was drastically elevated 1 hour after birth compared with the level just before birth, confirming our previous results that initial pulmonary respiration causes massive diaphragm injury in neonatal dystrophic dogs (Figure 2, A and B). Furthermore, we found that serum OPN was elevated in relation to muscle regeneration during the progressive phase, but not the chronic phase, when muscle regeneration is inactive. In mdx mice, the serum OPN level is increased at the ages of 4 and 16 weeks. Active immune cell infiltration and muscle regeneration are seen in muscle tissues in these mdx mice, but whether the serum OPN level is related to muscle regeneration has not been verified. During the muscle regeneration process induced by cardiotoxin injection, OPN expression was present in infiltrating immune cells and regenerating muscle fibers, and serum OPN tended to increase. These results support our idea that serum OPN reflects the activity of muscle regeneration in skeletal muscles in dystrophic dogs.

Next, we compared the serum OPN levels to levels of serum MMP-9, an indicator of muscle inflammation, and its inhibitor TIMP-1 to further confirm whether serum OPN was indicative of muscle regeneration or inflammation. OPN contributes to increased amounts of MMP-9 as an immunomodulator, but the serum levels of these two factors were not similarly elevated in the dystrophic dogs. The serum MMP-9 level in dystrophic dogs was significantly increased 1 hour after birth compared with the level just before birth, and the pattern was similar to that of serum CK but not OPN. MMP-9 appears to rapidly reflect the inflammatory response, which can be explained by the following two reasons: the latent MMP-9 form (ie, deposited in the extracellular matrix) can be quickly converted to the active form through a proteolytic cascade, and MMP-9 can be immediately released from actively infiltrating granulocytes due to storage of MMP-9 in the granules. In dystrophic dogs at the age of 3 months, both serum OPN and MMP-9 levels were significantly elevated compared with those in WT dogs. This consistent elevation actively reflects a serial change in muscle inflammation and regeneration. The elevation pattern of serum TIMP-1 was similar to that of serum OPN, and TIMP-1 expression was also observed in immune cells and regenerating muscle fibers in dystrophic muscles. Regarding the similar aspects of OPN and TIMP-1, these two factors may coordinately interact with each other in an MMP-independent manner. Indeed, TIMP-1 plays roles in the processes of cell growth, myogenesis, and fibrosis in addition to inhibiting MMP-9. However, serum TIMP-1 levels were not significantly different between dystrophic and WT dogs. Detection of serum OPN may be easier than detection of serum TIMP-1 in dystrophic dogs.

An important remaining question is whether we can use serum OPN as a novel biomarker in human DMD based on our dog results. The serum OPN level in dystrophic dogs was significantly correlated with the phenotypic severity at the onset of clinical signs, suggesting that serum OPN can
be related to dystrophic disease in the early phase. In a previous study, the serum OPN levels were not significantly different between patients with DMD and controls, whereas the serum MMP-9 and TIMP-1 levels were significantly increased.21 The limitation of their study is that they included DMD patients with high mean ages (13.1 ± 6.2 years; range, 2.9 to 31.2 years), and therefore, muscle regeneration was not expected to be active in those patients’ muscles. Indeed, muscle regeneration in skeletal muscles of patients with DMD becomes inactive around the age of 9 years.43 We propose that the serum OPN level should be analyzed in young patients with DMD. We expect that serum MMP-9 and TIMP-1 levels were significantly increased.21 The limitation of their study is that they included DMD patients with high mean ages (13.1 ± 6.2 years; range, 2.9 to 31.2 years), and therefore, muscle regeneration was not expected to be active in those patients’ muscles. Indeed, muscle regeneration in skeletal muscles of patients with DMD becomes inactive around the age of 9 years.43 We propose that the serum OPN level should be analyzed in young patients with DMD. We expect that serum MMP-9 and TIMP-1 levels were significantly increased.21

Finally, the cleaved form of OPN, which is cleaved by thrombin or MMP-3, -7, and -12, actively regulates cell behavior and has high affinity for multiple integrin subtypes in other inflammatory and neoplastic disorders. The ratios of thrombin-cleaved versus noncleaved OPN in rheumatoid arthritis are significantly increased in plasma and synovial fluid compared with plasma from healthy controls. We attempted to distinguish cleaved and noncleaved forms of OPN in canine serum and plasma samples. However, we found that this distinction was difficult because we performed sandwich ELISA assay with two polyclonal anticanine OPN antibodies against unidentified epitopes, but anticanine OPN antibodies against the N-terminal and C-terminal halves were not available, and separation according to molecular weight in immunoblotting was not able to be optimized in the serum or plasma samples because of excessive amounts of albumin, which yielded close molecular weight to noncleaved form of glycosylated OPN, although we excluded serum or plasma albumin with commercially available kits. As a next step, identification of the cleaved and noncleaved forms of OPN in the plasma of patients with DMD could be feasible by ELISA with commercial antihuman OPN antibodies against the N-terminal and C-terminal halves. Further analysis of each form could reveal the additional properties and roles of OPN in dystrophic disease.

In conclusion, serum OPN is a promising indicator of muscle regeneration in dystrophic dogs and may lead to the development of a novel biomarker for DMD. Moreover, serum OPN is expected to be applicable as a surrogate end point in clinical trials aimed at developing new treatments for DMD and other muscle disorders.
