ABSTRACT

We present measurements of the galaxy bias b and the galaxy–matter cross-correlation coefficient r for the Baryon Oscillation Spectroscopic Survey LOWZ luminous red galaxy sample. Using a new statistical weak lensing analysis of the Red Cluster Sequence Lensing Survey (RCSLenS), we find the bias properties of this sample to be higher than previously reported with b = 2.45±0.05 and r = 1.64±0.16 on scales between 3 and 20 arcmin. We repeat the measurement for angular scales of 20 arcmin ≤ θ ≤ 70 arcmin, which yields b = 2.39±0.07 and r = 1.24±0.25. This is the first application of a data compression analysis using a complete set of discrete estimators for galaxy–galaxy lensing and galaxy clustering. As cosmological data sets grow, our new method of data compression will become increasingly important in order to interpret joint weak lensing and galaxy clustering measurements and to estimate the data covariance. In future studies, this formalism can be used as a tool to study the large-scale structure of the Universe to yield a precise determination of cosmological parameters.

Key words: gravitational lensing: weak – methods: analytical – surveys.

1 INTRODUCTION

Since the discovery of the accelerated expansion of the Universe (Riess et al. 1998; Perlmutter et al. 1999), the origin and nature of dark energy remains unknown. Several possible explanations like a cosmological constant, quintessence, or a modification of gravity on cosmological scales have been suggested. Although the accelerated expansion has been confirmed using a combination of other cosmological probes like cosmic microwave background experiments (Hinshaw et al. 2013; Planck Collaboration XIII 2015), weak gravitational lensing (Schrabback et al. 2010; Heymans et al. 2013), galaxy clusters (Vikhlinin et al. 2009; Mantz et al. 2014), or baryon acoustic oscillations (BAO; Blake et al. 2012; Sánchez et al. 2013), the statistical power of these probes so far remains insufficient to reveal the true nature of dark energy. Statistical precision sufficient to distinguish a cosmological constant from a more dynamical nature of dark energy will only be reached by the next generation of cosmology experiments, like Euclid (Laureijs et al. 2011), the LSST (Ivezic et al. 2008), or WFIRST (Spergel et al. 2015). For this purpose, the Euclid satellite will not only map the whole extra-galactic sky in the optical and the near-infrared, but it will also take near-infrared spectra of about 50 million galaxies up to a redshift of z = 2. Using this vast data set, the Euclid consortium will measure the geometry of the Universe using both BAO and cosmic shear.

Cosmic shear is the distortion of light bundles from distant sources caused by the intervening tidal gravitational field, caused by the large-scale matter distribution in the Universe, which is measured from the auto-correlation of galaxy shapes (e.g. Bacon, Refregier & Ellis 2000; Van Waerbeke et al. 2001; Hoekstra et al. 2002a; see Bartelmann & Schneider 2001 for a review). The gravitational lensing signal in the galaxy shapes contributes only a few per cent to the whole galaxy ellipticity; furthermore, these galaxies are intrinsically small, typically smaller than the point spread function (PSF) of ground-based observations, and correspondingly are measured over a limited number of CCD pixels. Correcting for PSF effects and pixelization still poses a challenge to the astronomical community (e.g. Kitching et al. 2012; Mandelbaum et al. 2015). Due to these technical difficulties, it is important to have multiple independent weak lensing probes to map the density field in our Universe. A particularly promising approach is to combine information from galaxy auto-correlations (e.g. Blake et al. 2012; Sánchez et al. 2013) and galaxy–matter correlations (e.g. van Uitert et al. 2011, 2012; Velander et al. 2014). Significant effort has been made to develop a new theoretical framework for these

⋆ E-mail: abuddend@astro.uni-bonn.de (AB); Peter@astro.uni-bonn.de (PS); hendrik@astro.uni-bonn.de (HH)
measurements (e.g. Leauthaud et al. 2011; Cacciato et al. 2012; Eriksen & Gaztanaga 2015; Coupon et al. 2015).

A further challenge in relating observed signals to theoretical predictions stems from the difficulty in understanding baryonic physics, such as cooling, star formation, and feedback. This affects the statistical properties of the large-scale structure on small scales. A particularly interesting approach was therefore suggested by Blandford et al. (2010, henceforth B10) who introduced a new estimator $\Upsilon$ for clustering and lensing, which eliminates all small-scale contributions to the signals. This methodology was successfully applied to the Sloan Digital Sky Survey by Mandelbaum et al. (2013). The new estimator can be used to constrain cosmological parameters as well as the bias between galaxies and the dark matter distribution.

In this work, we show that the $\Upsilon$ statistic is a special case of the aperture mass formalism (Schneider 1996; Schneider et al. 1998). Using this information, we generalize the B10 approach; in particular, we define a complete set of estimators for a given range of scales which all are “blind” to the correlation functions below a pre-described threshold. We expect that the first few elements of this discrete set contain all the relevant information, which thus leads to a substantial data compression and a lower dimensional covariance, similar to the Complete Orthogonal Sets of E/B-mode Integrals (COSEBIs) statistic for cosmic shear (Schneider, Eifler & Krause 2010).

As a proof of concept, in this paper we fix the cosmology and use the new estimators to measure the galaxy bias of a particular galaxy sample. For this study, we use as lenses the galaxies from the Baryon Oscillation Spectroscopic Survey (BOSS) LOWZ sample (Eisenstein et al. 2011) and as sources photometrically selected background galaxies from the Red Cluster Sequence Lensing Survey (RCSLenS) Hildebrandt et al., in preparation. In order to establish the accuracy of the estimator and to create the corresponding covariance matrix, we use mock catalogues, which are based on the simulations by Harnois-Deraps & van Waerbeke (2015).

Galaxy bias describes how galaxies trace the underlying dark matter field (Kaiser 1984). In this analysis, we concentrate on the linear bias factor $b$, which is defined as the square root of the ratio of the galaxy to dark matter power spectra, and the galaxy–matter cross-correlation coefficient $r$. The bias of the LOWZ sample was measured in Chiang et al. (2013) and in a different way by Parejko et al. (2014), the bias of the CAMASS sample for example in Nuza et al. (2013). The WiggZ sample was analysed in Marin et al. (2013) using three-point correlation functions. Measuring these parameters is crucial for redshift-space-distortion studies as well as many cosmological measurements where $b$ and $r$ represent nuisance parameters.

This is the first measurement of galaxy bias using galaxy–galaxy lensing in RCSLenS, a re-analysis of the Red Cluster Sequence Survey 2 (RCS2; Gilbank et al. 2011). In van Uitert et al. (2015), a similar measurement has been carried out on RCS2 using correlation functions instead of the advanced statistics we introduce here. Blake et al. (2015) present galaxy–galaxy measurements on the RCSLenS data to constrain modified gravity. The focus of this study is to introduce a new methodology and the benefits of data compression taking galaxy bias measurements as an example.

This paper is organized as follows. In Section 2, we introduce the B10 method, our generalization, and the approach to measure the galaxy bias. Section 3 describes the data analysis, and in Section 4 we give a detailed discussion. As the fiducial cosmology we use a flat $\Lambda$ cold dark matter cosmology constrained by the Planck collaboration $H_0 = 67.74\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$, $\Omega_m = 0.3089$, $\Omega_\Lambda = 0.6911$, and $\sigma_8 = 0.8159$ (Planck Collaboration XIII 2015). To test the sensitivity of our results with respect to cosmological parameters, we also use the cosmology obtained in Heymans et al. (2013): $H_0 = 73.8\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$, $\Omega_m = 0.271$, $\Omega_\Lambda = 0.729$, and $\sigma_8 = 0.799$.

2 METHOD

2.1 The $\Upsilon$ statistics interpreted as $M_{ap}$

In B10 two new estimators were introduced, one in terms of the projected galaxy correlation function $o_{p}(\vartheta)$ and one in terms of the differential surface mass density $\Delta \Sigma$ around galaxies. This is measured using weak gravitational lensing, namely the tangential shear component $\gamma_t$. These estimators are simultaneously analysed in order to recover information about the dark matter distribution. In this section, we will generalize these estimators, but instead of $o_{p}$ and $\Delta \Sigma$ we will use the angular correlation function $o(\vartheta)$ and the tangential shear $\gamma_t(\vartheta)$ around (foreground) galaxies. These quantities can be obtained from large photometric lensing surveys where spectroscopic redshift information is not available. When using only photometric redshifts, measuring $o_p$ is not sensible. Nevertheless, for this proof-of-concept study, we make use of a spectroscopically selected galaxy sample. This simplifies the interpretation of the results since the spectroscopic sample has a well-defined redshift- and galaxy-type distribution. Furthermore, it is possible to measure the galaxy bias for such a sample by different means, like higher order clustering or redshift-space distortions. While measuring angular correlation functions for galaxies with spectroscopic redshifts might seem unnecessary, doing so makes this technique directly applicable to future photometric surveys that lack spectroscopy.

The estimator introduced by B10 in the case of the tangential shear $\gamma_t$ is:

$$\Upsilon(\vartheta, \vartheta_{\text{min}}) = \gamma_t(\vartheta) - \left( \frac{\vartheta_{\text{min}}}{\vartheta} \right)^2 \gamma_t(\vartheta_{\text{min}}),$$

where $\vartheta_{\text{min}}$ is the scale below which small-scale information is suppressed. There are two features in the definition of $\Upsilon(\vartheta, \vartheta_{\text{min}})$ which require attention. First, it is a continuous function of the scale $\vartheta > \vartheta_{\text{min}}$. In any analysis, the signal needs to be measured in bins of $\vartheta$. This means that the angular scale needs to be discretized when comparing measurements with theoretical predictions. It is usually unclear how this discretization is optimized, as there is a balance between having enough points to include all relevant cosmological information on the one hand and to limit the number of points for a manageable covariance matrix on the other hand. A second feature is the occurrence of $\gamma_t(\vartheta_{\text{min}})$ for every $\vartheta$ in $\Upsilon$, which means that any uncertainty in this quantity will affect $\Upsilon(\vartheta, \vartheta_{\text{min}})$ at all scales $\vartheta$. Furthermore, as the tangential shear at a fixed angular separation cannot be measured, but must be averaged over a finite interval, this can introduce systematics in the measurement of $\gamma_t(\vartheta_{\text{min}})$, and thus the $\Upsilon(\vartheta, \vartheta_{\text{min}})$. In fact, Mandelbaum et al. (2013) determined $\gamma_t(\vartheta_{\text{min}})$ by a power-law fit of the tangential shear (more precisely, of $\Delta \Sigma$) over a finite interval bracketing both sides of the minimum scale.

---

---

2 As mentioned before, B10 actually define $\Upsilon$ in terms of $\Delta \Sigma$. To be consistent throughout the paper, we use $\gamma_t$. Thus, we denote the B10 statistics in terms of $\gamma_t$ as $\Upsilon$.  

Here we address all these issues, by first relating the \( \hat{\gamma} \) statistic to the aperture mass (Schneider 1996), which is defined as

\[
M_{ap} = \int_{\phi_{\min}}^{\phi_{\max}} d\phi \phi \ U(\phi) \kappa(\phi),
\]

where \( \kappa(\phi) \) is the convergence, azimuthally averaged over polar angle and over the foreground galaxy population, \( U \) is a compensated filter function, i.e.

\[
\int_{\phi_{\min}}^{\phi_{\max}} d\phi \phi \ U(\phi) = 0,
\]

and \( \phi_{\min} \) and \( \phi_{\max} \) the inner and outer scales on which the weight function is non-zero. The aperture mass can be expressed in terms of the azimuthally averaged tangential shear \( \gamma \), yielding

\[
M_{ap} = \int_{\phi_{\min}}^{\phi_{\max}} d\phi \phi \ Q(\phi) \gamma(\phi),
\]

where \( Q \) is related to \( U \) via

\[
Q(\phi) = \frac{2}{\phi^2} \int_{0}^{\phi} d\phi' \phi' \ U(\phi') - U(\phi).
\]

For every value of \( \theta \), we can interpret \( \hat{\gamma} \) as an aperture mass. Indeed, comparing equation (4) with equation (1), we see immediately that \( \hat{\gamma}(\theta, \phi_{\min}) \) is a special case of \( M_{ap} \) if we set \( \phi_{\min} = \theta_{\min}, \phi_{\max} = \theta \), and

\[
Q(\phi) = + \frac{1}{\phi} \delta_0(\phi - \theta) - \frac{\theta_{\min}}{\theta} \delta_0(\phi - \theta_{\min}),
\]

where \( \delta_0 \) is the Dirac delta function. Inverting equation (5), we find

\[
U(\phi) = -Q(\phi) + 2 \int_{\phi}^{\infty} d\phi' \frac{Q(\phi')}{\phi'},
\]

which yields

\[
U(\phi) = -\frac{1}{\phi} \delta_0(\phi - \theta) + \frac{\theta_{\min}}{\theta} \delta_0(\phi - \theta_{\min})
+ \frac{2}{\phi^2} \left[ \mathcal{H}(\phi - \theta) - \mathcal{H}(\theta_{\min} - \theta) \right],
\]

where \( \mathcal{H} \) is the Heaviside step function. This equation shows that the \( \hat{\gamma} \) statistics is indeed insensitive to changes in the filter functions. We decide to use the Legendre polynomials as they already have many of the desired properties for the filter functions. For this to work, we define the transformation used in Schneider et al. (2010)

\[
x = \frac{2(\theta - \bar{\theta})}{\Delta \theta},
\]

with \( \Delta \theta = \theta_{\max} - \theta_{\min}, \bar{\theta} = (\theta_{\min} + \theta_{\max})/2 \), and \( d\theta = \frac{\Delta \theta}{2} dx \). This maps the interval \([\theta_{\min}, \theta_{\max}]\) to \([-1, 1]\). Setting

\[
U_n(\theta) = \frac{1}{(\Delta \theta)^n} u_n \left( \frac{2(\theta - \bar{\theta})}{\Delta \theta} \right),
\]

where we explicitly impose the dependence on \( x \) and normalize by \( 1/(\Delta \theta)^2 \), so that the \( U_n \) have correct units. This transforms the compensation and orthogonality conditions into

\[
\int_{-1}^{1} dx \left( x \frac{\Delta \theta}{2} + \bar{\theta} \right) u_n(x) = 0
\]

and

\[
\int_{-1}^{1} dx \ u_n(x) u_m(x) = \delta_{nm},
\]

where in the latter case we fixed the normalization of the filter functions. The Legendre polynomials can be defined via the recurrence relation

\[
P_{n+1}(x) = \frac{1}{n+1} \left[ (2n+1) x P_n(x) - n P_{n-1}(x) \right],
\]

with \( P_0(x) = 1 \) and \( P_1(x) = x \). We first try to find dimensionless filters \( u_n(x) \) which are proportional to the \( P_n(x) \); these can then be transformed into the \( U_n(\theta) \) according to equation (12). The first function to fulfill our two conditions is a first-order polynomial of the form \( u_1(x) = a_1 x + a_0 \), where the two coefficients \( a_1 \) are determined from the two conditions, to yield

\[
u_1(x) = \frac{3Gx - 1}{\sqrt{2(1 + 3G^2)}},
\]

where we defined \( G = 2\bar{\theta} / \Delta \theta \). Since

\[
\int_{-1}^{1} dx \ P_n(x) x^m = 0
\]

for \( m < n \) and because the Legendre polynomials are orthogonal, we can choose for \( n \geq 2 \) the filter functions

\[
u_n(x) = \sqrt{\frac{2n + 1}{2}} P_n(x) \mathcal{H}(1 - x^2),
\]
which has the correct normalization, and we explicitly included the finite interval of support for the $u_n$. Using equation (12), we then find

$$U_n(\theta) = \frac{1}{(\Delta \theta)^2} u_n(x)$$

$$= \frac{1}{(\Delta \theta)^2} \sqrt{\frac{2n+1}{2}} P_n \left( \frac{2(\theta - \bar{\theta})}{\Delta \theta} \right)$$

$$\times \mathcal{H}(\theta - \theta_{\text{max}}) \mathcal{H}(\theta_{\text{max}} - \theta),$$

(19)

for $n \geq 2$ and

$$U_n(\theta) = \frac{1}{(\Delta \theta)^2} \sqrt{\frac{2n+1}{2}} \mathcal{H}(\theta - \theta_{\text{min}}) \mathcal{H}(\theta_{\text{max}} - \theta),$$

(20)

The $Q_n(\theta)$ follow immediately as

$$Q_n(\theta) = \frac{2}{\theta^2} \int_{\theta_0}^\theta d\theta' \theta' U_n(\theta') - U_n(\theta).$$

(21)

The final estimators for galaxy–matter correlations define the cross-correlation coefficient between the galaxies and the underlying matter distribution. Thus, we define integrals of the galaxy angular correlation function that have the same angular dependence as the filter functions for the convergence $\kappa$, i.e.

$$\gamma_{\text{gg}}(n) = \int_{\theta_{\text{min}}}^{\theta_{\text{max}}} d\theta \theta Q_n(\theta) \gamma_\ell(\theta).$$

(22)

We want to compare the clustering of galaxies with the galaxy–galaxy lensing signal, to learn about the biasing of galaxies and the cross-correlation coefficient between the galaxies and the underlying matter distribution. Thus, we define integrals of the galaxy angular correlation function that have the same angular dependence as the filter functions for the convergence $\kappa$, i.e.

$$\gamma_{\text{gg}}(n) = \int_{\theta_{\text{min}}}^{\theta_{\text{max}}} d\theta \theta U_n(\theta) \omega(\theta).$$

(23)

Note that the clustering signal will be measured using the lens sample from galaxy–galaxy lensing in order to probe the same density field. During our analysis, we will make use of only the first three orders of the filter functions; for our data set, those should contain all relevant information. The corresponding filter functions for $\theta_{\text{min}} = 3 \text{ arcmin}$ and $\theta_{\text{max}} = 20 \text{ arcmin}$ are displayed in Figs 1 and 2.

\section{Connecting observables to theory}

In order to constrain cosmological parameters or to measure the bias factor, we need to know how the observables $\gamma_{ij}(n)$ are connected to predictable theoretical quantities like the three-dimensional dark matter power spectrum $P_{3D}(k, w)$, where $k$ is the comoving wavenumber and $w$ the comoving distance, characterizing the cosmic epoch. This is now shown for the case where the lens sample has a rather broad redshift distribution, as for increasingly small distributions the following approximations for the angular correlations diverge and are not valid any more.

In the following, we assume that the bias is linear and can be described by

$$\hat{b}^2 = \frac{P_{3D}}{P_{3D}}.$$

(24)

with $P_{3D}(k, w)$ being the galaxy power spectrum. This assumption is valid on large scales which we explicitly limit ourselves to with the $\gamma$ formalism. Furthermore, we define the cross-correlation coefficient

$$\hat{r} = \frac{P_{3D}}{\sqrt{P_{3D} P_{3D}}},$$

(25)

where $P_{3D}(k, w)$ is the cross-power spectrum between matter and galaxies. $\hat{r}$ is important for determining the galaxy–matter cross-correlations.

The angular correlation function of galaxies is related to $P_{3D}$ through (Hoekstra et al. 2002b)

$$\omega(\theta) = \frac{1}{2\pi} \int dw \left( \frac{p_{\text{gg}}(w)}{f_{\text{g}}(w)} \right)^2$$

$$\times \int d\ell \, \ell \hat{b}^2(\ell, z) P_{3D} \left( \frac{\ell}{f_{\text{g}}(w)}; w \right) J_0(\ell \theta),$$

(26)

where $\hat{b}(\ell, z)$ is the galaxy bias as a function of angular wavenumber $\ell = k f_{\text{g}}(w)$ and redshift $z$, $w$ the comoving distance, $f_{\text{g}}(w)$ the comoving angular diameter distance, $p_{\text{gg}}(w)$ the lens probability distribution in terms of $w$, and $J_0$ the zeroth-order Bessel function of the first kind. Changing the order of integration and replacing the probability distribution with respect to $w, p_{\text{gg}}(w)$, by the observable
redshift distribution, using \( p_w(z)dz = p_w(w)dw \), yields

\[
\omega(\theta) = \frac{1}{2\pi} \int d\ell \int dw J_0(\ell \theta) \frac{d_\ell}{dw} \frac{\hat{b}(\ell,z)}{f_\ell(w)} \mathcal{P}_{3D} \left( \frac{\ell}{f_\ell(w)}; w \right),
\]

with

\[
\frac{d_\ell}{dw} = H_0 \sqrt{(1+z)^3(1+z\Omega_M) - z(2+z)\Omega_L}.
\]

By inserting equation (27) into equation (23), we obtain an expression for \( \gamma_\ell(n) \), which depends quadratically on the galaxy bias

\[
\gamma_\ell(\theta) = \frac{3 \Omega_m}{4\pi} \left( \frac{H_0}{c} \right)^2 \int d\ell \int dw \frac{g(w)p_w(w)}{a(w)f_\ell(w)} \frac{d_\ell}{dw} \hat{b}(\ell,z) \mathcal{P}_{3D} \left( \frac{\ell}{f_\ell(w)}; w \right) J_2(\ell \theta),
\]

where \( \hat{b} \) is the cross-correlation coefficient, \( a(w) \) is the cosmic scale factor, and \( g(w) \) is the mean of angular diameter distances (e.g. Schneider et al. 1998)

\[
g(w) = \int_{w}^{\infty} dw' \frac{p_v(w')f_\ell(w' - w)}{f_\ell(w')},
\]

with \( p_v(w) \) the source distance probability distribution in terms of \( w \). Again, by changing the order of integration and inserting the redshift distribution into equation (22), one finds

\[
\gamma_{gm}(n) = \frac{3 \Omega_m}{4\pi} \left( \frac{H_0}{c} \right)^2 \frac{br}{\Omega_m} \int d\ell \int dw J_2(\ell \theta) \frac{g(w)p_v(z)}{a(w)f_\ell(w)} \frac{d_\ell}{dw} \mathcal{P}_{3D} \left( \frac{\ell}{f_\ell(w)}; w \right).
\]

As before, we use the weighted average of \( \hat{b} \) and \( \hat{r} \) over \( \ell \), \( z \), and \( \theta \). When measuring \( \gamma_{gm}(n) \) and \( \gamma_{\ell}(n) \) from the data, we can simultaneously fit the models to both signals. In this way, we can either

(i) fix the cosmology and constrain \( b \) and \( r \),
(ii) fix \( b \) and \( r \) and constrain the cosmology,
(iii) set \( r = 1 \) and fit \( b \) and the cosmology simultaneously,
(iv) or constrain \( b \), \( r \), and the cosmology simultaneously.

3 When constraining \( b \) later on, we will actually constrain an average over \( n \), \( \ell \), and \( z \).

3.1 Data sets

3.1.1 BOSS LOWZ

We measure the weak lensing signal around galaxies from BOSS (Eisenstein et al. 2011), using the 10th Data Release (Ahn et al. 2014). We select galaxies following Chuang et al. (2013) and Sánchez et al. (2013) to select a spectroscopic redshift sample with \( 0.15 \leq z \leq 0.43 \). This yields 9102 galaxies within the RCSLenS footprint. For the lensing measurements, we only use the BOSS galaxies that lie within the BOSS–RCSLenS overlap; however, for the clustering measurement, the whole LOWZ sample is used, which is spread over a much larger area (\(~5000\) deg\(^2\); Tojeiro et al. 2014) and consists of 218 891 galaxies. In this way, we can make use of the much better statistics arising from the larger sample.

The latter is possible by combining galaxy clustering and galaxy–galaxy lensing with a cosmic shear signal, weighted by the same kernel functions \( \mathcal{U}_e(\theta) \). Since the scope of this work is to prove the concept, we will use a fixed cosmology and constrain the galaxy bias \( b \) and the cross-correlation coefficient \( r \).

3 DATA ANALYSIS

We choose to apply our new methodology to determine a large-scale bias measurement of the BOSS LOWZ sample. This sample is well suited for this first analysis, as there are already measurements and it is less complicated compared to a whole cosmological study.

3.1 Data sets

3.1.1 BOSS LOWZ

We measure the weak lensing signal around galaxies from BOSS (Eisenstein et al. 2011), using the 10th Data Release (Ahn et al. 2014). We select galaxies following Chuang et al. (2013) and Sánchez et al. (2013) to select a spectroscopic redshift sample with \( 0.15 \leq z \leq 0.43 \). This yields 9102 galaxies within the RCSLenS footprint. For the lensing measurements, we only use the BOSS galaxies that lie within the BOSS–RCSLenS overlap; however, for the clustering measurement, the whole LOWZ sample is used, which is spread over a much larger area (\(~5000\) deg\(^2\); Tojeiro et al. 2014) and consists of 218 891 galaxies. In this way, we can make use of the much better statistics arising from the larger sample. This is a valid approach as in Section 3.4 we show that the signals measured for both samples are consistent with each other. The BOSS and RCSLenS overlapping area is shown in Fig. 3. The summed \( p_v(z) \) derived from spectroscopic redshifts of the lenses can be seen in Fig. 4. For the clustering measurements, we make use of the weights, \( \Theta \), provided by the BOSS collaboration, which account for fibre collisions as explained in Anderson et al. (2014).

3.1.2 RCSLenS

RCSLenS (Hildebrandt et al., in preparation) is an analysis of the original RCS2 using the Canada–France–Hawaii Telescope Lensing...
The lensing signal around random points. The coloured lines show the signal for every region, whereas the black solid line shows the average. Furthermore, we display the measured signal of $\gamma_i$ around BOSS LOWZ galaxies as the dashed black line. The shaded regions correspond to the 1σ errors. The strongest random signal corresponds to CDE0133, which is the smallest region in the area we use, and thus it has the smallest impact on the total signal. For the measurements, we subtract the signal for each region separately.

galaxy (for more details see e.g. Miller et al. 2013 or Hildebrandt et al., in preparation). We apply the $m$-correction as an ensemble correction in order to avoid correlations between the correction and the intrinsic shape of the galaxy (Miller et al. 2013)

$$\langle \gamma^\text{cal} (\vartheta) \rangle = \frac{\langle \gamma (\vartheta) \rangle}{1 + K(\vartheta)},$$

where

$$1 + K(\vartheta) = \sum_i \eta_i \Theta_i (1 + m_i) \sum_j \eta_j \Theta_j.$$

As before, $\eta_i$ denotes the $\text{lensfit}$ weight of the $i$th source galaxy and $\Theta_i$ the BOSS weight of the $j$th lens galaxy, whereas $\epsilon_{\ell, i, j}$ is the tangential ellipticity of the $i$th source with respect to the $j$th lens. For selecting source galaxies, we only use the six RCSLenS regions that have four-band photometry and sufficient overlap with BOSS. Those are CDE0133, CDE0047, CDE1645, CDE2329, CDE1514, and CDE2143. This leaves us with about 170 deg$^2$ in area and 4657 415 source galaxies. As sources we select all galaxies with a $\text{lensfit}$ weight $\eta > 0$ that are outside of masks. We use the posterior redshift distribution for each source galaxy, estimated with the photometric redshift code $\text{BPZ}$ (Benítez 2000), to find the summed $p_\eta (z)$ of the sources, which is displayed in Fig. 4.

The shear measurements for RCSLenS suffer from a multiplicative bias as well as an additive bias so that

$$\langle \epsilon_{\text{obs}} \rangle = (1 + \langle m \rangle) \langle \epsilon_{\text{true}} \rangle + c,$$

as explained for example in Miller et al. (2013). Here $\epsilon_{\text{obs}}$ is the observed ellipticity of a galaxy image, $\epsilon_{\text{true}}$ the sheared intrinsic ellipticity, $1 + m$ the correction factor for the multiplicative bias ($m$-correction), and $c$ the correction for the additive bias ($c$-correction). We correct the measured shapes of galaxies for the multiplicative bias using the factor $(1 + m)$ determined for every area and create shape and photometry catalogues. The survey was carried out using Megacam at the Canada–France–Hawaii Telescope (CFHT) and has only one exposure per band per pointing. It covers roughly 500 deg$^2$ in the $g'$, $r'$, $i'$, and $z'$ bands and with an additional 250 deg$^2$ with three or fewer bands. The $r'$ band is used as the lensing band with a $\sigma$ point source limiting magnitude of $m_{\text{lim}} = 24.3$ and a median seeing of 0.71 arcsec (Gilbank et al. 2011). Galaxy shapes are measured using $\text{lensfit}$ (Miller et al. 2013). As described in Blake et al. (2015) we use the $\text{lensfit}$ weights $\eta$ and the BOSS weights $\Theta$ for the lensing analysis. We take both weights in order to use the same weighting scheme in the lensing as well as in the clustering analysis. The resulting estimator is

$$\langle \gamma (\vartheta) \rangle = \sum_{i, j} \sum_{i, j} \eta_i \Theta_j \epsilon_{\ell, i, j}. \tag{32}$$

Here $\eta_i$ denotes the $\text{lensfit}$ weight of the $i$th source galaxy and $\Theta_j$ the BOSS weight of the $j$th lens galaxy, whereas $\epsilon_{\ell, i, j}$ is the tangential ellipticity of the $i$th source with respect to the $j$th lens. For selecting source galaxies, we only use the six RCSLenS regions that have four-band photometry and sufficient overlap with BOSS. Those are CDE0133, CDE0047, CDE1645, CDE2329, CDE1514, and CDE2143. This leaves us with about 170 deg$^2$ in area and 4657 415 source galaxies. As sources we select all galaxies with a $\text{lensfit}$ weight $\eta > 0$ that are outside of masks. We use the posterior redshift distribution for each source galaxy, estimated with the photometric redshift code $\text{BPZ}$ (Benítez 2000), to find the summed $p_\eta (z)$ of the sources, which is displayed in Fig. 4.

The shear measurements for RCSLenS suffer from a multiplicative bias as well as an additive bias so that

$$\langle \epsilon_{\text{obs}} \rangle = (1 + \langle m \rangle) \langle \epsilon_{\text{true}} \rangle + c,$$  

as explained for example in Miller et al. (2013). Here $\epsilon_{\text{obs}}$ is the observed ellipticity of a galaxy image, $\epsilon_{\text{true}}$ the sheared intrinsic ellipticity, $1 + m$ the correction factor for the multiplicative bias ($m$-correction), and $c$ the correction for the additive bias ($c$-correction). We correct the measured shapes of galaxies for the multiplicative bias using the factor $(1 + m)$ determined for every region separately.

For the weighted average source density, we find $\sim 5.1$ galaxies/arcmin$^2$ when using

$$n_{\text{eff}} = \frac{1}{A_{\text{eff}}} \left( \sum_i \eta_i \right)^2 \sum_i \eta_i^2, \tag{36}$$

as defined in Heymans et al. (2012), where $A_{\text{eff}} = 174.32$ deg$^2$ is the total unmasked area in the BOSS–RCSLenS overlap. We use this definition to account for the fact that we use the $\text{lensfit}$ weight in the analysis. The RCSLenS catalogues are also subject to

\[ \begin{array}{c}
\frac{L}{A} \\
\frac{M}{N}
\end{array} \]
a blinding scheme. In order to avoid confirmation bias, the galaxy ellipticities exist in four versions A, B, C, and D. One of them is the true measured one, whereas the rest have been changed by a small factor as described in Hildebrandt et al. (in preparation) for RCSLenS and in Kuijken et al. (2015) for the Kilo Degree Survey. This analysis has been performed four times using different the ellipticity versions. After the analysis had been finished, the lead author contacted the external blinder, Matthias Bartelmann, who revealed which catalogue was the truth. We then used the results of the true measured ellipticities only. No changes were made after ‘unblinding’. For more information about RCSLenS and the data production process, we refer to Hildebrandt et al. (in preparation).

3.2 Mock catalogues

In order to estimate the covariance of the γs, we make use of the simulations described in Harnois-Deraps & van Waerbeke (2015). Those have box sizes of 505 h−1 Mpc, 15363 particles each and are on 30722 grids, which are projected onto 12 2882 pixels. The light cones are then extracted from those onto 60002 pixels grids. The cosmology used is Ωm = 0.2905, ΩΛ = 0.7095, σ8 = 0.826, and H0 = 68.98 km s−1 Mpc−1. The slight difference to the cosmologies we use will introduce a small systematic error in the covariance, which we will neglect in this study.

Based on these simulations, we use a set of mock catalogues designed to match the properties of the RCSLenS sources and the BOSS LOWZ lenses. They specifically match the ellipticity and redshift distributions of RCSLenS and the clustering properties of the LOWZ sample. We apply photometric redshift scatter to the mock sources through a zspec−zphot matrix calibrated from the BOSS redshift probability distributions. The mock LOWZ lenses are added to the simulation using a halo occupation distribution (HOD) approach calibrated by matching the observed clustering amplitude. In total, we use 360 mock catalogues, which are 60 deg2 each. The size of the region used for the mocks is just determined by the size of the simulations themselves. We do not aim to simulate the whole survey area, but for practicality we area-scale the covariance from the 60 deg2 outputs. Using six of the mocks, we can create one mock survey, assuming that each of the six RCSLenS regions fits within the 60 deg2. This then results in 60 mock realizations of RCSLenS. Whenever the regions are too big, we use them as much area as possible and scale the covariance accordingly by using the ratio of the area of the mock region and the real region. Furthermore, for the covariance estimation we use only the BOSS–RCSLenS overlap for the measurements of the clustering signal, whereas for the data we use the whole BOSS area. In order to account for this, we rescale the clustering part of the covariance with the ratio of the two areas. Additionally, we set the cross-covariance between γgg and γgm to 0, as the BOSS–RCSLenS overlap is just a small fraction of the whole BOSS area. This has been shown to be a valid approach by More et al. (2015), who conduct similar measurements with BOSS and the CFHTLenS catalogues. In the end, we have 60 mock surveys, to which we apply the same masks as for the data set. For this, we neglect that the mocks assume a flat sky, as the resulting differences are clearly negligible compared to the statistical error of our measurements given the small extent of each region.

3.3 Measuring two-point correlations

Before we can determine the compressed observables γθ(n), we first need to measure the corresponding galaxy–galaxy lensing and galaxy clustering signals. We choose to measure these in two intervals

(i) 3 arcmin ≤ θ ≤ 20 arcmin,
(ii) 20 arcmin ≤ θ ≤ 70 arcmin

in 200 linear bins. The centre of the first range corresponds to a comoving length of ∼3 Mpc at a redshift of z ≈ 0.29, and the second one to a comoving length of ∼12 Mpc. These are both large scales, which will enable us to measure the large-scale bias of the LOWZ sample. As a cross-check, we also determine these signals for a larger angular scale in larger logarithmic bins. The 200 linear bins will later be used for determining the γθ. For ω(θ), we use the Landy–Szalay estimator (Landy & Szalay 1993). We show the mean signals for γθ and ω measured in the mocks together with the real data in Fig. 6. Those measurements are in good agreement.
A new estimator for galaxy–matter correlations

Figure 8. The top panels show the measured $\Upsilon_{gm}$ and $\Upsilon_{gg}$ and the best fit using one of the two cosmologies. The magenta and dark blue lines are the connections between the predicted data points using the Planck or the CFHTLenS cosmology. In the bottom panels, we show the residuals $(\Upsilon_{\text{obs}} - \Upsilon_{\text{model}})/\Delta\Upsilon_{\text{obs}}$, where $\Delta\Upsilon_{\text{obs}}$ is the uncertainty in the measured $\Upsilon$. Left: measurements for the 3–20 arcmin interval. Clearly, on these scales the model we adopt to describe the galaxy bias is not a good description of the data shown here, especially the clustering data. For more details, see Section 3.4 Right: measurements for the 20–70 arcmin interval.

Figure 9. Top: the angular correlation function within the small-scale interval, the corresponding model for $b = 1$, and the best-fitting model. This best-fitting model has been determined from a joint fit of $\Upsilon_{gm}$ and $\Upsilon_{gg}$. Bottom: the square root of the ratio between the measured $\alpha(\theta)$ and the model one, which is an estimator for $b$. Apparently, in contradiction to our assumption, there is a scale dependence of $b$. This is why the data shown in the left-hand panel of Fig. 8 are not well described by the model. A variation of $b$ of about 5 per cent within this interval would already be enough to reconcile the data and the model. The data shown here correspond to the Planck cosmology measurements.

3.4 $\Upsilon_{gm}(n)$ and $\Upsilon_{gg}(n)$

We use $\gamma_t(\theta)$ and $\alpha(\theta)$ measured in the 200 linear bins and integrate them using equations (22) and (23) in order to find $\Upsilon_{gm}(n)$ and $\Upsilon_{gg}(n)$. Here we only compute the first three orders. At the end of our analysis, we tested how the parameter constraints on $b$ and $r$

Figure 10. Top: the tangential shear function within the small-scale interval, the corresponding model for $b, r = 1$, and the best-fitting model. This best-fitting model has been determined from a joint fit of $\Upsilon_{gm}$ and $\Upsilon_{gg}$. Bottom: the ratio between the measured $\gamma_t(\theta)$ and the model one, which is an estimator for $b \times r$. Due to the larger uncertainties, the shear measurements do not show a preference for scale-dependent bias. Additionally, we also show the corresponding estimate for $r$, if we use $b$ as estimated in Fig. 9. The data shown here correspond to the Planck cosmology measurements.

changed with the number of $\Upsilon$ orders used. We found no significant difference for up to five orders and decided to use three orders, which yields a sufficient number of data points for our analysis and still benefits from a low-dimensional covariance. The fact that we do not find a decrease of parameter uncertainty with increasing number of orders shows that the first few orders indeed contain all the relevant information (see Fig. 7 for more details). The measured data points for both angular intervals are presented in Fig. 8. Unlike
correlation function measurements, these \( \Upsilon \) data points cannot be interpreted easily. However, it is clear that in the large-scale interval the model (see Section 2) is a very good fit to the data regardless of the cosmological parameters used.\(^4\) This is not the case for the smaller scale interval, where one of the clustering data points is several \( \sigma \) away from the best-fitting model. Clearly, the assumption of linear bias on these non-linear scales is not valid for the clustering data. This is partly due to the small uncertainties in these measurements as well as the fact that we neglect the model uncertainties. As can be seen in Fig. 9, a change of \( b \) of about 5 per cent within this interval would already be enough to reconcile the data with the model. If model uncertainties had been included in this figure, it is likely that data and model would be in line again. Another possible explanation of the discrepancy between data and model in this case could be that the fiducial cosmology is wrong. Furthermore, we also investigate if an indication for a scale-dependent bias can be found in the \( \gamma(\theta) \) data in Fig. 10 and find no such preference.

From the 60 mock realizations, we compute the \( \Upsilon_{\text{gm}} \) and \( \Upsilon_{\text{gg}} \) covariance matrix by measuring the signals for each mock survey. For the inverse covariance, we take into account the correction factor from Hartlap, Simon & Schneider (2007), which prevents us from underestimating the uncertainty in the parameter estimates. The correlation matrices for all measurements are shown in Fig. 11. The covariance matrix is then used for a maximum likelihood analysis, in which we simultaneously fit theoretical predictions to \( \Upsilon_{\text{gm}} \) and \( \Upsilon_{\text{gg}} \) with the galaxy bias \( b \) and the cross-correlation coefficient \( r \) as free parameters. We compute the predictions from equations (28) and (31) using the 3D matter power spectrum computed with NICA (Kilbinger et al. 2009), which uses the recipe from Smith et al. (2003). The resulting likelihood contours are displayed in Fig. 12. We perform this fit twice using the Planck cosmology as well as the best-fitting cosmology from CFHTLenS, constrained in

\(^4\) Note that the data points are highly covariant (see also Fig. 11).
Figure 12. The $1\sigma$, $2\sigma$, and $3\sigma$ parameter constraints on the galaxy bias parameter $b$ and $r$ for the BOSS LOWZ galaxy sample as well as the marginalized likelihoods of $b$ and $r$. The black ellipse, if shown, is the $1\sigma$ contour of the corresponding measurement using a Planck cosmology from the upper two panels. These parameters were constrained by a maximum likelihood fit to the $\Upsilon_{gm}$ and $\Upsilon_{gg}$. All constraints agree within $1\sigma$. Top left: likelihood contours for the $3$–$20$ arcmin interval using a Planck cosmology. Top right: likelihood contours for the $20$–$70$ arcmin interval using a Planck cosmology. Middle left: likelihood contours for the $3$–$20$ arcmin interval using the Heymans et al. (2013) cosmology. Middle right: likelihood contours for the $20$–$70$ arcmin interval using the Heymans et al. (2013) cosmology. Bottom left: likelihood contours for the $3$–$20$ arcmin interval using a Planck cosmology and the $0.15 < z < 0.3$ lens sample. Bottom right: likelihood contours for the $3$–$20$ arcmin interval using a Planck cosmology and the $0.3 < z < 0.43$ lens sample.

Heymans et al. (2013), to test for the dependence of the parameters on different cosmologies. The results are presented in Table 1. For the maximum likelihood analysis, we assume a Gaussian likelihood function. Note that one cannot directly interpret the $\chi^2$/d.o.f. values since the model is non-linear and the data noisy (Andrae, Schulz-Hartung & Melchior 2010). We find $b = 2.45^{+0.05}_{-0.05}$ and $r = 1.64^{+0.17}_{-0.16}$ for the small-scale interval, and for angular scales of $20$ arcmin $\leq \theta \leq 70$ arcmin we find $b = 2.39^{+0.07}_{-0.07}$ and $r = 1.24^{+0.26}_{-0.25}$.

The estimated values for $b$ are slightly higher compared to the findings by Parejko et al. (2013), who determine the bias by fitting their projected clustering signal to HOD populated $N$-body simulations. Using their best-fitting model and the
3.5 Redshift evolution test: splitting up the LOWZ sample

In Fig. 13, we show the measured signals for $\gamma(\theta)$ and $\omega(\theta)$ for the whole sample as well as for the two subsamples (described below). We also scale the expected signals for both with the constrained values of $b$ and $r$. The data are consistent with constant values of $b$ and $r$, and the values for both parameters obtained from the fit to the $\gamma$s are consistent with the signals of the correlation functions $\gamma(\theta)$ and $\omega(\theta)$. This means that the method introduced here is indeed capable of compressing the data while not losing information contained in the correlation functions.

Furthermore, we conduct a redshift evolution test where we split up the lens sample into two subsamples with $0.15 < z < 0.3$ and $0.3 < z < 0.43$. In this way, we can test if the model is capable of describing these measurements in a proper way. We then make the same measurements as before using the Planck cosmology and the $\theta \in [3\,\text{arcmin}, 20\,\text{arcmin}]$ interval. This yields two new estimates for $b$ and $r$. We find $b = 2.35^{+0.04}_{-0.07}$ and $r = 1.84^{+0.24}_{-0.23}$ for the low-redshift sample and $b = 2.61^{+0.08}_{-0.06}$ and $r = 1.33^{+0.21}_{-0.20}$ for the high-redshift one. They are also shown in Table 1. The measured correlation functions are displayed in Fig. 13 and the likelihood contours in Fig. 12. We find that $r$ becomes smaller for the higher redshift sample, whereas $b$ gets larger. All estimates are, however, consistent with the parameters determined using the whole sample. In fact, the two subsample values for $b$ and $r$ bracket their whole sample counterparts.

4 DISCUSSION AND OUTLOOK

We introduced a new estimator for galaxy clustering, $\gamma_{gm}$, and for galaxy–galaxy lensing, $\gamma_{lm}$. Those are generalizations of the methods introduced and tested in B10 and Mandelbaum et al. (2013), respectively. The estimators are a discretization of the $\gamma(\theta, \theta_{\text{min}})$, which leads to substantial data compression and thus a lower dimensional covariance, while still eliminating the sensitivity to the matter distribution on small scales. Especially, lowering the dimension of the data covariance increases the accuracy in its measurement for a fixed number of mock realizations. Recall that the number of mock realizations needed to find a good estimate of the covariance increases with the number of data points. We applied this method to data using the BOSS LOWZ sample as lenses and galaxies from the RCSLenS as sources. While fixing the cosmology, we performed a simultaneous fit to $\gamma_{gm}$ and $\gamma_{lm}$ with $b$ and $r$ as free parameters. For different angular scales as well as different assumed cosmologies, we find $b$ slightly higher than the findings of Parejko et al. (2013) and Chuang et al. (2013). This tension could be resolved if our assumption of scale-independent bias was a poor approximation to the true galaxy bias of this sample, as both of the studies mentioned allow for scale-dependent bias.

On large angular scales, the cross-correlation coefficient $r$ is found to be compatible with unity, as expected for the corresponding spatial scales (e.g. B10). On the smaller angular scale interval, we find a value for $r$ that is significantly larger than unity, most likely due to a different scale and redshift dependence of the various power spectra that enter the $\gamma$s in equations (28) and (31), and our definition of the ‘effective’ coefficients $b$ and $r$ as an average of the three-dimensional bias and correlation coefficients $\hat{b}$ and $\hat{r}$. If one had already measured values for $b$ and $r$, this method can even be used for cosmological studies. In these studies, it will be necessary to find out how many orders of $\gamma$ are sufficient to extract all cosmological information from the signal. As in this work it was not possible to do so as all information is already contained in the first few orders, due to our simplified bias models. This might change in a cosmological analysis from substantially larger data sets with more complex models.

Summarizing, the new estimators presented in this paper are promising tools for future large-scale structure studies, especially given their advantageous abilities concerning data compression and the dimension of the data covariance.

ACKNOWLEDGEMENTS

We are grateful to the RCS2 team for planning the survey, applying for observing time, and conducting the observations. We would like to thank Matthias Bartelmann for being our external blinder, revealing which of the four catalogues analysed was the true unblinded catalogue at the end of this study. We would also like to thank Christopher Morrison and Patrick Simon for fruitful discussions. Also, we would like to thank our anonymous referee for constructive comments. We acknowledge use of the Canadian Astronomy Data Centre operated by the Dominion Astrophysical Observatory for the National Research Council of Canada’s Herzberg Institute of

Table 1. Parameter estimates for galaxy $b$ and cross-correlation coefficient $r$. In the case of the full sample, the second column indicates the cosmology used. For the samples used in Section 3.5, it indicates which subsample was used.

A new estimator for galaxy–matter correlations

**Figure 13.** Galaxy clustering and galaxy–galaxy lensing signals with the best-fitting theoretical model for the 3—20 arcmin interval using a Planck cosmology. The two sub-samples from the redshift evolution test are used as well as the full sample. The best-fitting lines were fitted to the $\Upsilon_s$, not the signals shown here. Within the fitting range, the estimated parameter values for $b$ and $r$ appear to be in excellent agreement with the data. We also show $\gamma_\mathrm{x}$, which is consistent with zero in all cases. A non-zero $\gamma_\mathrm{x}$ points to systematic issues in the data.

APPENDIX A: ESTIMATING $\gamma_x$

For weak gravitational lensing measurements, it is important to check if the cross shear, $\gamma_x$, is consistent with zero. If not so, this points to systematic issues in the data. We can conduct a similar test for the $\gamma_{gm}(n)$, where we replace $\gamma_x$ with $\gamma_x$ in equation (22),

$$\gamma_x(n) = \int_{\theta_{\min}}^{\theta_{\max}} \, d\theta \, \theta \, Q_x(\theta) \gamma_x(\theta).$$

As $\gamma_x$ needs to be zero on all scales, so does its compressed counterpart $\gamma_x$. We estimated $\gamma_x$ for all six measurements described in this paper and show the signal in Fig. A1. Indeed, we find it to be consistent with zero for all three orders.

Figure A1. We present the $\gamma_x$ for all six measurements conducted in this paper. We find it to be always consistent with zero.
