Abstract

The hot QCD matter produced in any heavy ion collision with a nonzero impact parameter is produced within a strong magnetic field. We study the imprint the magnetic fields produced in non-central heavy ion collisions leave on the azimuthal distributions and correlations of the produced charged hadrons. The magnetic field is time-dependent and the medium is expanding, which leads to the induction of charged currents due to the combination of Faraday and Hall effects. We find that these currents result in a charge-dependent directed flow $v_1$ that is odd in rapidity and odd under charge exchange. It can be detected by measuring correlations between the directed flow of charged hadrons at different rapidities, $(v_1^+(y_1)v_1^+(y_2))$.

Keywords: Magnetohydrodynamics; Quark gluon plasma; Heavy ion collisions

1. Introduction

Strong magnetic fields $\vec{B}$ are produced in all non-central heavy ion collisions (i.e. those with nonzero impact parameter $b$) by the charged “spectators” (i.e. the nucleons from the incident nuclei that “miss”, flying past each other rather than colliding). Indeed, estimates obtained via application of the Biot–Savart law to heavy ion collisions with $b = 4$ fm yield $e|\vec{B}|/m_π^2 \approx 1–3$ about 0.1–0.2 fm/c after a RHIC collision with $\sqrt{s} = 200$ AGeV and $e|\vec{B}|/m_π^2 \approx 10–15$ at

Secondly, the field has currents directed in the collision direction, to produce an expansion force on the charge. Fig. 1.

Hall state of the nuclear system is due to the expanded magnetic field produced in the collision points in the \( +z \) (\( -z \)) direction at positive (negative) \( z \). We take the impact parameter vector to point in the \( x \) direction, choosing the nucleus moving toward positive (negative) \( z \) to be located at negative (positive) \( x \), which is to say taking the magnetic field \( \vec{B} \) to point in the \( +y \) direction. The direction of the electric currents due to the Faraday and Hall effects is shown, as is the direction of the directed flow of positive charge (dashed) in the case where the Faraday effect is on balance stronger than the Hall effect.

Some even earlier time after an LHC collision with \( \sqrt{s} = 2.76 \) ATeV [1–7]. In recent years there has been much interest in consequences of these enormous magnetic fields present early in the collision that are observable in the final state hadrons produced by the collision, see for example, [1,8–10].

In Ref. [11] we analyze what are surely the simplest and most direct effects of magnetic fields in heavy ion collisions, and quite likely also their largest effects, namely the induction of electric currents carried by the charged quarks and antiquarks in the quark–gluon plasma (QGP) and, later, by the charged hadrons. The source of these charged currents is twofold. Firstly, the magnitude of \( \vec{B} \) varies in time, decreasing as the charged spectators fly away along the beam direction, receding from the QGP produced in the collision. The changing \( \vec{B} \) results in an electric field due to Faraday’s law, and this in turn produces an electric current in the conducting medium. Secondly, because the conducting medium, i.e. the QGP, has a significant initial longitudinal expansion velocity \( \vec{u} \) parallel to the beam direction and therefore perpendicular to \( \vec{B} \), the Lorentz force results in an electric current perpendicular to both the velocity and \( \vec{B} \), akin to the classical Hall effect. Fig. 1 serves to orient the reader as to the directions of \( \vec{B} \) and \( \vec{u} \), and the electric currents induced by the Faraday and Hall effects. The net electric current is the sum of that due to Faraday and that due to Hall. If the Faraday effect is stronger than the Hall effect, that current will result in directed flow of positively charged particles in the directions shown in Fig. 1 and directed flow of negatively charged particles in the opposite direction. Our goal in Ref. [11] is to make an estimate of the order of magnitude of the resulting charge-dependent \( v_1 \) in the final state pions. We make various simplifying assumptions, explained below.
In order to obtain the velocity $\vec{v}$ associated with the charged currents due to the electromagnetic field, we first calculate the magnetic and electric fields themselves, $\vec{B}$ and $\vec{E}$, by solving Maxwell’s equations in the center-of-mass frame (the frame illustrated in Fig. 1). The electromagnetic field produced by a single point-like charge moving with a velocity $\vec{v}$ in a medium with constant (our first simplifying assumption) conductivity $\sigma$ can be calculated analytically [11]. The total field is obtained by integrating this over the entire distribution of all the protons in the two colliding nuclei. We also make the simplifying assumption that the protons in a nucleus are uniformly distributed within a sphere of radius $R$, with the centers of the spheres located at $x = \pm b/2$, $y = 0$ and moving along the $+z$ and $-z$ directions. For the participants we use the empirical distribution [1,12]. We find [11] that, as other authors have shown previously [2–7], the presence of the conducting medium delays the decrease in the magnetic field.

To model the expanding medium we use the analytic solution to relativistic viscous hydrodynamics for a conformal fluid with the shear viscosity to entropy density ratio given by $\eta/s = 1/(4\pi)$ found by Gubser in 2010 [13]. The solution describes a finite size plasma produced in a central collision that is obtained from conformal hydrodynamics by demanding boost invariance along the beam (i.e. $z$) direction, rotational invariance around $z$, and two special conformal invariances perpendicular to $z$. As demonstrated in [11], we can choose parameters such that Gubser’s solution yields a reasonable facsimile of the pion and proton transverse momentum spectra observed in RHIC and LHC collisions with 20–30% centrality, corresponding to collisions with a mean impact parameter between 7 and 8 fm, see e.g. [14,15]. We denote the velocity of Gubser’s solution as $\vec{u}$.

Given the electromagnetic field and the velocity of the medium $\vec{u}$ in the center-of-mass frame, we then determine the total velocity $\vec{V}$ of the charged particles (u and d quarks) as follows. Making the assumption $|\vec{V} - \vec{u}|/|\vec{u}| \ll 1$ (justified a posteriori) we first boost to the local fluid rest frame at that point in spacetime, namely the (primed) frame in which $\vec{u}' = 0$ at that point. In the primed frame all components of the electromagnetic field $\vec{E}'$ and $\vec{B}'$ are non-vanishing. We then solve the equation of motion for a charged fluid element with mass $m$ in this frame, using the Lorentz force law and requiring stationary currents:

$$m \frac{d\vec{v}'}{d\tau} = q \vec{v}' \times \vec{B}' + q \vec{E}' - \mu m \vec{v}' = 0,$$

where the last term describes the drag force on a fluid element with mass $m$ on which some external (in this case electromagnetic) force is being exerted, with $\mu$ being the drag coefficient. The nonrelativistic form of (1) is justified by the aforementioned assumption. For the purpose of our order-of-magnitude estimate, we use the $\mathcal{N} = 4$ SYM value [16–18] $\mu m = 6.8 T^2$, for a ’t Hooft coupling $\lambda = 6\pi$ and $T = 255$ MeV. Finally, we boost back to the original center-of-mass frame to obtain the total velocity $\vec{V}$.

The theoretical estimations we make here are based on the basic assumption that the electromagnetic interactions can be treated classically. We checked this by comparing the total magnetic energy in the medium to the energy of a single photon with wavelength comparable to the size of the medium and showing that the former is larger roughly by a factor that varies from $\sim 1000$ to $\sim 50$ as $\tau$ increases from 0.3 fm to 0.8 fm.

2. Results

We apply the standard prescription to obtain the hadron spectra from a hydrodynamic flow, that is here given by Gubser’s solution, assuming sudden freezeout when the fluid cools to a
specified freezeout temperature \(T_f\), was developed by Cooper and Frye [19]. We shall take \(T_f = 130\) MeV for heavy ion collisions at both the LHC and RHIC. The hadron spectrum for particles of species \(i\) with mass \(m_i\) will depend on transverse momentum \(p_T\), momentum space rapidity \(Y\) and the azimuthal angle in momentum space \(\phi_p\). To establish notation, note that the dependence of the hadron spectrum on \(\phi_p\) can be expanded as

\[
S_i \equiv p^0 \frac{d^3N_i}{dp^3} = \frac{d^3N_i}{p_T dp_T d\phi_p} = v_0 (1 + 2v_1 \cos(\phi_p - \pi) + 2v_2 \cos 2\phi_p + \cdots),
\]

where in general the \(v_n\) will depend on \(Y\) and \(p_T\).

Once we obtained the electromagnetic field, fixed the parameters of the hydrodynamic flow and calculated the total velocity \(V^{\pm \mu}\) as explained in the previous section, we can finally use the freezeout procedure to calculate the hadron spectra, including electromagnetic effects. Fig. 2 shows \(v_1\) for positively and negatively charged pions as a function of momentum-space rapidity \(Y\) at transverse momenta \(p_T = 0.5, 1, 2\) GeV. We have chosen the initial magnetic field created by the spectators with beam rapidity \(\pm Y_0 = \pm 8\) (LHC), \(\pm Y_0 = \pm 5.4\) (RHIC) and the participants, we have chosen the electric conductivity \(\sigma = 0.023\) fm\(^{-1}\) and the drag parameter \(\mu m\) in (1) as above and we have set the freezeout temperature to \(T_f = 130\) MeV. We see in Fig. 1 that if the current induced by Faraday’s law is greater than that induced by the Hall effect, we expect \(v_1 > 0\) for negative pions at \(Y > 0\) and for positive pions at \(Y < 0\) and we expect \(v_1 < 0\) for positive pions at \(Y > 0\) and for negative pions at \(Y < 0\). Comparing to Fig. 2, we observe that this is indeed the pattern for pions with \(p_T = 1\) GeV, meaning that in the competition between the Faraday and Hall effects, the effect of Faraday on pions with \(p_T = 1\) GeV is greater than the effect of Hall. However, the effects of Hall and Faraday on pions with smaller \(p_T\) and small \(Y\) are comparable in magnitude, for example with the Hall effect just larger for \(p_T = 0.25\) and \(|Y| < 1.2\), resulting in a reversal in the sign of \(v_1\) in this kinematic range at LHC. We observe that the Faraday effect is dominant for pions at RHIC even for \(p_T\) as low as 0.25 GeV. Overall the effect is larger at RHIC than at LHC by an order of magnitude. This may be attributed to the fact that the magnetic flux at the time we initiate hydrodynamics is larger at RHIC. Directed flow
for the protons and anti-protons at the LHC and RHIC can be calculated in a similar fashion and the result can be found in [11].

3. Observables, and a look ahead

Our estimates of the magnitude of the charge-dependent directed flow of pions in heavy ion collisions at the LHC and RHIC, and their dependence on $Y$ and $p_T$, can be found in Fig. 2. The effect is small. What makes it distinctive is that it is opposite in sign for positively and negatively charged particles of the same mass, and that for any species it is odd in rapidity. Detecting the effect directly by measuring the directed flow of positively and negatively charged particles, which we shall denote by $v^+_1$ and $v^-_1$, is possible in principle but is likely to be prohibitively difficult in practice [11]. Instead, it would be advantageous to define correlation observables that, first of all, involve taking ensemble averages of suitably chosen differences rather than just of $v^+_1$ or $v^-_1$ and that, second of all, do not require knowledge of the direction of the magnetic field. To isolate the charge-dependent directed flow that we are after, it is helpful to define the asymmetries between the directed flows for positive and negative hadrons $A^{ij}_1(Y_1, Y_2) \equiv v^+_1(Y_1) - v^-_1(Y_2)$, where $i, j$ are $+$ or $-$. Even if the direction of the magnetic field is not reconstructed, one can still study the correlation functions defined by

$$C_{ijkl}^{ij}(Y_1, Y_2) \equiv \langle A^{ij}_1(Y_1, Y_2) A^{kl}_1(Y_1, Y_2) \rangle. \quad (3)$$

These correlation functions are quadratic in the directed flow, and so are not sensitive to the direction of $\vec{B}$ and the sign of $v_1$ in a given event. However, they still carry the requisite information about dynamical charge-dependent correlations induced by the magnetic field. Analogous correlations functions have been measured with high precision [20,21].

The challenge to experimentalists is to measure these correlators, or others that are also defined so as to separate the desired effects from charge-independent backgrounds. If this is possible, one may use comparisons between data and the nontrivial $p_T$- and $Y$-dependence of results like those that we have obtained in Fig. 2 to extract a wealth of information, for example about the strength of the initial magnetic field and about the magnitude of the electrical conductivity of the plasma.
