Robust self-testing of many-qubit states

Anand Natarajan*  Thomas Vidick†

October 13, 2016

Abstract

We introduce a simple two-player test which certifies that the players apply tensor products of Pauli $\sigma_X$ and $\sigma_Z$ observables on the tensor product of $n$ EPR pairs. The test has constant robustness: any strategy achieving success probability within an additive $\epsilon$ of the optimal must be $\text{poly}(\epsilon)$-close, in the appropriate distance measure, to the honest $n$-qubit strategy. The test involves $2n$-bit questions and 2-bit answers. The key technical ingredient is a quantum version of the classical linearity test of Blum, Luby, and Rubinfeld.

As applications of our result we give (i) the first robust self-test for $n$ EPR pairs; (ii) a quantum multiprover interactive proof system for the local Hamiltonian problem with a constant number of provers and classical questions and answers, and a constant completeness-soundness gap independent of system size; (iii) a robust protocol for delegated quantum computation.

1 Introduction

Quantum non-local games lie at the intersection of several areas of quantum information. They provide a natural approach to device-independent certification or self-testing of unknown quantum states. Device-independent certification has applications to quantum cryptography, from quantum key distribution [VV14, MS14] to delegated computation [RUV13, FH15]. The key idea behind these applications is that certain nonlocal games, such as the CHSH game [CHSH69], provide natural statistical tests that can be used to certify that an arbitrary quantum device implements a certain “strategy” specified by local measurements on an entangled state (e.g. an EPR pair).

A common weakness of all existing self-testing results is that their performance scales poorly with the number of qubits of the state that is being tested. Given a self-test, define (somewhat informally) its robustness as the largest $\epsilon = \epsilon(\delta)$ such that a success probability at least $\omega_{\text{opt}} - \epsilon$ in the test certifies the target state up to error (in trace distance and up to local isometries) at most $\delta$, where $\omega_{\text{opt}}$ is the success probability achieved by an ideal strategy. All previously known tests for $n$-qubit states required $\epsilon \ll \text{poly}(\delta, 1/n)$.

Our main result is a form of robust self-test for any state that can be characterized via expectation values of tensor products of standard Pauli $\sigma_X$ or $\sigma_Z$ observables. (This includes a tensor product of $n$ EPR pairs; see below.)

Theorem 1 (simplified). Let \( \mathcal{P} \) be a set of \( n \)-qubit observables, each of which is a tensor product of single-qubit Pauli \( \sigma_X, \sigma_Z \) or \( \pm I \), and \( \lambda_{\text{max}} = \| E_{\mathcal{P}} [P] \| \). For any \( \eta \geq 0 \) there exists a \( p = p(\eta) = \Theta(\eta^c) \), where \( 0 < c < 1 \) is a universal constant, and a 7-player nonlocal game with \( O(n) \)-bit questions and \( O(1) \)-bit answers such that
\[
\omega_{\text{opt}}^* = \frac{1}{2} + p \lambda_{\text{max}} \pm \eta.
\]

We view the theorem as a robust self-test in the following sense. Suppose a many-qubit state \( |\psi\rangle \) can be characterized as the leading eigenvector of an operator \( O = E_{\mathcal{P}} [P] \) obtained as the average of \( n \)-qubit Pauli operators, with associated eigenvalue \( \lambda_{\text{max}} \in [-1, 1] \). For example, if \( \mathcal{P} \) is the uniform distribution over \( \{ \sigma_X \otimes \sigma_X, \sigma_Z \otimes \sigma_Z \}^\otimes n \) then \( \lambda_{\text{max}} = 1 \) and the leading eigenvector is the tensor product of \( n \) EPR pairs. More generally, if \( H \) is a local Hamiltonian with \( m \) local \( XZ \) terms we can take \( \mathcal{P} \) to be \( I \) with probability \( \frac{1}{2} \) and the negation of a random term of \( H \) with probability \( \frac{1}{2} \). Then \( \lambda_{\text{max}} = \frac{1}{2} - \frac{1}{2m} \lambda_{\text{min}}(H) \) and the leading eigenvector is a ground state of \( H \).

Theorem 1 provides a nonlocal game such that the optimal success probability in the game is directly related to \( \lambda_{\text{max}} \), thereby providing a test distinguishing between small and large \( \lambda_{\text{max}} \).

In fact the complete statement of the theorem (see Theorem 23 in Section 5) says much more. In particular, we provide a complete characterization (up to local isometries) of strategies achieving a success probability at least \( \omega_{\text{opt}}^* = \epsilon \), for \( \epsilon \) sufficiently small but independent of \( n \), showing that such strategies must be based on a particular encoding (based on a simple, fixed error-correcting code) of an eigenvector associated to \( \lambda_{\text{max}} \).

1.1 Applications

Before giving an overview of the proof of the theorem we discuss some consequences of the theorem that help underscore its generality.

Hamiltonian complexity. A first consequence of Theorem 1 is that the ground state energy of a local Hamiltonian can be certified via a non-local game with questions of polynomial length and constant-length answers.

Corollary 2. Let \( H \) be an \( n \)-qubit Hamiltonian that can be expressed as a weighted sum, with real coefficients, of tensor products of \( \sigma_X \) and \( \sigma_Z \) operators on a subset of the qubits, and normalize \( H \) such that \( \| H \| \leq 1 \). Suppose it is given that \( \lambda_{\text{min}}(H) \leq a \) or \( \lambda_{\text{min}}(H) \geq b \) for some \( 0 \leq a < b \leq 1 \). There exists a one-round interactive proof protocol between a classical polynomial-time verifier and 7 entangled provers where the verifier’s (classical) questions are \( O(n/(b-a)) \) bits long, the provers’ (classical) answers are \( O(1) \) bits each, and the maximum probability that the verifier accepts is
\[
\lambda_{\text{min}} \leq a \implies \omega_{\text{opt}}^* \geq p_c := \frac{1}{2} + 2 \eta_0, \quad \lambda_{\text{min}} \geq b \implies \omega_{\text{opt}}^* \leq p_s := \frac{1}{2} + \eta_0,
\]
where \( \eta_0 > 0 \) is a small (universal) constant.

Since the class of Hamiltonians considered in Corollary 2 is QMA-complete [CM14], the corollary can be viewed as a quantum analogue of the (games variant of the) exponentially long PCP based on the linearity test of Blum, Luby and Rubinfeld [BLR93]. Indeed, observe that the game

\[\text{The complete statement of the theorem says much more, and provides a characterization of near-optimal strategies.}\]
constructed in the corollary has an efficient verifier, polynomial-length questions, and a constant completeness-soundness gap \( \eta_0 \) as soon as the original promise on the ground state energy for the Hamiltonian exhibits an inverse-polynomial completeness-soundness gap. The derivation of Corollary 2 from Theorem 1 involves a step of gap amplification via tensoring, and relies on the fact that Theorem 1 allows any \( XZ \)-Hamiltonian with no requirement on locality.

A similar result to Corollary 2 was obtained by Ji \[Ji16\], and we build on Ji’s techniques. The results are incomparable: on the one hand, the question size in our protocol is much larger (\( \text{poly}(n) \) bits instead of \( O(\log n) \) for \[Ji16\]); on the other hand, the dependence of the verifier’s acceptance probability on the ground state energy is much better, as in \[Ji16\] the completeness-soundness gap remains inverse polynomial.

**An exponential quantum PCP.** The expert reader may already have noted that the complexity-theoretic formulation of Corollary 2, described above already follows from known results in quantum complexity. Indeed, recall that the class QMA is in PSPACE, and that single-round multi-prover interactive proof systems for PSPACE (and even NEXP) follow from the results in \[IV12, Vid13\]. Another possible proof approach for the same result could be obtained by repeating the protocol in \[Ji16\] a polynomial number of times; provided there existed an appropriate parallel repetition theorem this would amplify the soundness to a constant (although the answer length would now be polynomial). In fact, based on a recent result by Ji \[Ji16b\] it seems likely that both approaches, based either on our results or parallel repetition of \[Ji16b\], could lead to an exponential “quantum-games” PCP for all languages in NEXP (instead of just QMA). Even though in purely complexity-theoretic terms the result would still not be new, we believe that the techniques from Hamiltonian complexity developed to obtain it show good promise for further extensions.

Indeed our protocol has some advantages over the generic sequence of known reductions. One is efficiency: in our protocol the provers merely need access to a ground state of the given local Hamiltonian and the ability to perform constant-depth quantum circuits. It is this property that enables our application to delegated quantum computing (see below for more on this). Answers in our protocol are a constant number of bits; the reductions mentioned above would require soundness amplification via parallel repetition, which would lead to answers of (at least) linear length.

Even though they may not provide the most immediately compelling application of Theorem 1, the complexity-theoretic consequences of Corollary 2 tie our results to one of their primary motivations, the quantum PCP conjecture. Broadly speaking, the quantum PCP research program is concerned with finding a robust analog of the Cook-Levin theorem for the class QMA. The “games variant” of this conjecture states that estimating the optimal winning probability of entangled players in a multiplayer nonlocal game, up to an additive constant, is QMA-hard. In other words, that there exists an MIP\(^*\) protocol for QMA with \( O(\log(n)) \)-bit messages and constant completeness-soundness gap. The best progress to date in this direction is the work of Ji \[Ji16a\], which gives a five-prover one-round MIP\(^*\) protocol with \( O(\log(n)) \)-bit messages for the local Hamiltonian problem such that the verifier’s maximum acceptance probability is \( a - b\lambda_{\text{min}}(H)n^{-c} \) for positive constants \( a, b, c \). This falls short of the games PCP conjecture in that the completeness-soundness gap is inverse polynomial in \( n \), rather than constant.\(^2\)

Our results suggest an approach to the problem from a different angle: we provide a “gap

\(^2\)Here again we point the interested reader to the recent \[Ji16b\], which obtains a protocol with similar parameters, involving 8 provers, for all languages in NEXP.
preserving” protocol, in the sense that the completeness-soundness gap is a polynomial function of the underlying promise gap of the Hamiltonian, but independent of the system size \( n \). However, this occurs at the cost of much longer messages — polynomial instead of logarithmic.

Dimension witnesses. Consider the operator \( O = \left( \frac{1}{2}(\sigma^X \otimes \sigma^X + \sigma^Z \otimes \sigma^Z) \right)^\otimes n \). This operator has largest eigenvalue 1 with associated eigenvector \(|\text{EPR}^\otimes n\rangle\), where \(|\text{EPR}\rangle = \frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle\). In this case the proof of Theorem 1 allows us to obtain the following robust self-test for \(|\text{EPR}^\otimes n\rangle\):

**Corollary 3.** For any integer \( n \) there is a two-player game with \( O(n) \)-bit questions and \( O(1) \)-bit answers such that (i) there is a strategy with optimal winning probability \( \omega^\ast \) that uses \(|\text{EPR}^\otimes n\rangle\) as entangled state; (ii) for any \( \epsilon > 0 \), any strategy with success probability at least \( \omega^\ast - \epsilon \) must be based on an entangled state which is (up to local isometries) within distance \( \delta = \text{poly}(\epsilon) \) of \(|\text{EPR}^\otimes n\rangle\).

The game whose properties are summarized in Corollary 3 is based on the CHSH game. By using the Magic Square game instead, it is possible to devise a test with perfect completeness, \( \omega^\ast = 1 \), which can be achieved using an honest strategy based on the use of \((n + 1)\) EPR pairs.

To the best of our knowledge, all prior self-tests for any family of states had a robustness guarantee going to 0 inverse polynomially fast with the number of qubits tested (see Section 1.3 below for a more thorough comparison with related works).

Delegated computation. It was noticed in [FH15] that an interactive proof system for the local Hamiltonian problem can also be used for delegated quantum computation with so-called post-hoc verification. The key idea is to use the Feynman-Kitaev construction to produce a Hamiltonian encoding the desired computation; measuring the ground energy of this Hamiltonian reveals whether the computation accepts or rejects. Following the same connection, we are able to give a post-hoc verifiable delegated computation scheme with a purely classical verifier and a constant number of provers. The provers only need the power of BQP. The scheme has a constant completeness-soundness gap independent of the size of the circuit to be computed, unlike the scheme of [FH15] and the classical scheme of [RUV13], which both have inverse-polynomial gaps. However, unlike the scheme of [RUV13], our protocol is not blind: the verifier must reveal the entire circuit to be computed to all the provers before the verification process starts. We refer to Section 6 for more details on this application.

1.2 Proof overview

The proof of Theorem 1 builds on ideas from complexity theory and quantum information. We draw inspiration from classical ideas in the closely related areas of probabilistically checkable proofs, locally testable codes, and property testing. The link between these areas and quantum self-testing is the idea of verifying a global property of an unknown object using only limited measurements. The two most important components of the proof are a “locally verifiable” encoding of arbitrary \( n \)-qubit quantum states [FV15], and a quantum analogue of the linearity test of Blum et al. [BLR93]. Since the second component is the more novel we explain it first.

Linearity testing of quantum observables. The simplest instantiation of the classical PCP theorem relies on the Hadamard code to robustly encode an \( n \)-bit string (e.g. an assignment to an instance of 3-SAT). Under this code, a string \( u \in \{0, 1\}^n \) is encoded as the \( 2^n \)-bit long truth table
of the function \( f_u : \{0,1\}^n \to \{-1,1\} \) given by \( f_u(x) = (-1)^u \cdot x \), where \( \cdot \) is the bitwise inner product. The function \( f_u(x) \) is said to be linear, since \( f_u(x + y) = f_u(x)f_u(y) \). The key property of the Hadamard code which makes it useful in this context is that it is locally testable. A local test is given by the BLR linearity test: given query access to a function \( f : \{0,1\}^n \to \{-1,1\} \), by checking that \( f(x + y) = f(x)f(y) \) at randomly chosen \( x, y \) the test certifies that any \( f \) that is accepted with probability at least \( 1 - \epsilon \) has the form \( f \approx_{\epsilon} f_u \) for some \( u \in \{0,1\}^n \), where \( f_u : a \mapsto (-1)^u a \) and \( \approx_{\epsilon} \) designates equality on an \((1 - O(\epsilon))\) fraction of inputs.

Here is a “quantum” reformulation of this test as a nonlocal game: instead of querying an oracle for \( f \) at three points, play a three-player nonlocal game where each player is asked for the value at a point. This test is sound even if the players share an entangled quantum state [IV12], but success in the test does not certify quantum behavior: the players could win with certainty just by sharing a description of a classical linear function \( f_u \); indeed, the main point of the analysis in [IV12] is precisely to ensure that provers sharing entanglement have no more freedom than to use it as shared randomness in selecting \( u \).

In contrast, we seek an extension of the test which certifies a very specific type of quantum behavior that could not be emulated by classical means alone: specifically, that the observable \( O_z \) measured by a player upon receiving question \( x \) itself is (up to a change of basis, and in the appropriate “state-dependent” norm) close to \( \otimes_i \sigma^z_{X_i} \). We give a test which achieves this. The test performs a combination of a linearity test in the \( X \)-basis and a linearity test in the \( Z \)-basis; an “anticommutation game” (which can be taken to be a version of the CHSH or Magic Square games) is used to constrain how the results of the two linearity tests relate to each other.

**Theorem 4** (Pauli braiding test, informal). There exists a two-player nonlocal game, based on the combination of (i) a linearity test in the \( X \) basis (questions \( x \in \{0,1\}^n \)); (ii) a linearity test in the \( Z \) basis (questions \( z \in \{0,1\}^n \)); (iii) an “anticommutation game” (based on e.g. the CHSH or Magic Square games) designed to test for generalized anti-commutation relations (questions \( (x,z) \in \{0,1\}^{2n} \)), such that any strategy that has success probability \( \omega^{opt}_{\chi} - \epsilon \) for some \( \epsilon > 0 \) must be based on observables \( A(x), A(z), A(x,z) \) and an entangled state \( |\psi\rangle_{AB} \) such that up to local isometries

\[
A(x) \approx_{\delta} \otimes_i \sigma^x_{X_i}, \quad A(z) \approx_{\delta} \otimes_i \sigma^z_{Z_i}, \quad \text{and} \quad |\psi\rangle_{AB} \approx_{\delta} |EPR\rangle_{AB}^\otimes n,
\]

where \( \delta = \text{poly}(\epsilon) \).

Neither the linearity test nor the anticommutation test alone would be sufficient to achieve the conclusion: as noted above, the linearity test can be passed even by classical provers, and our anticommutation test can be fooled if the provers share just one EPR pair. Rather, it is the guarantees provided by these tests together that enable us to create a tensor-product structure in the provers’ Hilbert space.

To gain intuition on the test one may think of it in the following way. A standard approach to self-testing \( n \) EPR pairs is to fix a decomposition of the Hilbert space as

\[
\mathcal{H} = \mathbb{C}^{2n} \approx \mathbb{C}^2 \otimes \cdots \otimes \mathbb{C}^2,
\]

and perform the CHSH (or Magic Square) test “in parallel”, on each copy of \( \mathbb{C}^2 \). To the best of our knowledge such test only leads to robustness bounds with a polynomial dependence in \( n \). In contrast the test on which Theorem4 is based relies on the observation that the decomposition (4) need not be rigidly fixed a priori; indeed there are many bases in which such decomposition of
In tensor factors can be performed. In particular, any pair of anti-commuting observables on \( H \) suffices to specify a copy of \( \mathbb{C}^2 \), on which a CHSH test can in principle be performed (here we crucially rely on rotation invariance of the \( 2^n \)-dimensional maximally entangled state). Our test leverages this observation by performing a CHSH test for each possible pair of Pauli operators \((\sigma_X(a), \sigma_Z(b))\), where \( a, b \in \{0, 1\}^n \) are such that \( a \cdot b = 1 \). Each of these tests amounts to identifying a copy of \( \mathbb{C}^2 \) and performing the CHSH test on it. Contrary to the parallel-repeated CHSH test these copies are not independent, and this is what makes our test much more robust.

**Encoding quantum states.** The second component of the proof of Theorem 1 is a procedure, first introduced in [FV15, Ji16a], for encoding an \( n \)-qubit quantum state in a constant number of \( n \)-qubit shares such that certain properties of the encoded state (such as expectation values of local Pauli observables) can be verified through a classical interaction with provers each holding one of the shares. This is akin to how the “games” variant of the classical PCP theorem is derived from the “proof-checking” variant: while in the classical setting a proof can be directly shared across multiple provers, in the quantum setting we use a form of secret-sharing code that allows for distributing quantum information.

This procedure is efficient in that the total number of tests that can be performed (equivalently, the number of questions) is polynomial in \( n \). However, the test in [FV15, Ji16a] is not robust, and is only able to provide meaningful results for values of \( \epsilon \) that scale inverse-polynomially with \( n \). By extending the Pauli braiding test, Theorem 4 to the stabilizer framework of [Ji16a] we obtain a procedure which is meaningful for constant \( \epsilon \). The drawback is that the provers may now be asked to measure all their qubits, and questions have length linear in \( n \); however the total effort required of the classical verifier (and of provers given access to the state) remains polynomial in the size of the instance.

1.3 Related work

We build on a number of previous works in quantum information and complexity theory. Motivation for the problem we consider goes back to a question of Aharonov and Ben-Or (personal communication, 2013), who asked how a quantum generalization of the exponential classical PCP could look like if it was not derived through the “circuitous route” obtained as the compilation of known but complex results from the theory of classical and quantum interactive proof systems (as described earlier). In this respect we point to [AAV13, Section 5] for a very different approach to the same question based on a “quantum take” on the arithmetization technique.

More directly, our work builds on the already-mentioned works [FV15, Ji16a] initiating the study of entangled-prover interactive proof systems for the local Hamiltonian problem. The idea of using a distributed encoding of the ground state in order to obtain a multiprover interactive proof system for the ground state energy is introduced in [FV15]. In that work the protocol required the provers to return qubits; the possibility for making the protocol purely classical was uncovered by Ji [Ji16a]. Our use of stabilizer codes, and the stabilizer test which forms part of our protocol, originate in his work. In addition we borrow from ideas introduced in the study of quantum multiprover interactive proofs with entangled provers [KM03, CHTW04], and especially the three-prover linearity test of [IV12] and the use of oracularization from [IKM09] to make it into a two-prover test.

Our results are related to work in quantum self-testing, in particular testing EPR pairs [MYS12].
and more general entangled states \cite{McK14}. A sequence of results has established that the presence of \( n \) EPR pairs between two provers can be certified via a protocol using queries and answers of length polynomial in \( n \), with inverse-polynomial completeness-soundness gap. This was first achieved by \cite{RUV13} for a test based on serial repetition of the CHSH game, and subsequently by \cite{McK15} for a single-round test based on CHSH, by \cite{OV16} for an XOR game based on CHSH, and by \cite{CN16} and \cite{Col16} independently for the parallel-repeated Magic Square game. Viewed in the context of these results our work is the only one to provide a test whose robustness does not depend on the number of EPR pairs being tested. The reason this can be achieved is the linearity test(s) performed as part of the Pauli braiding test, which we see as a major innovation of our work.

1.4 Open questions and future directions

In our opinion the most important direction for future work is to improve the efficiency of the Pauli braiding test in terms of the number of questions required. Can the test be derandomized, to questions of sub-linear, or even logarithmic, length? Such a result would establish the main step left towards proving the games variant of the quantum PCP conjecture. Instead of directly derandomizing the current test, can it be made more robust, perhaps using some of the ideas based on low-degree polynomial encodings that are key to the classical PCP theorem?

Aside from this challenging problem, there are several open questions that we find interesting and may be more approachable.

1. In the classical PCP setting, the Hadamard code and the BLR linearity test can be used for alphabet reduction: converting a PCP or MIP protocol with large answer alphabet into one with a binary alphabet. This is a key step in Dinur’s proof of the PCP theorem \cite{Din07}. Can the linearity test also be used for alphabet reduction of MIP\(^*\) protocols? The difficulty is to preserve completeness; if the optimal honest strategy uses a maximally entangled state then the adaptation should be straightforward, but if not it may be more challenging — perhaps ideas similar to our protocol for ground states of XZ Hamiltonians can be used.

2. An obvious application for many EPR pairs is quantum key distribution (QKD). A major contribution of \cite{RUV13} was to show that the sequential self-test for many EPR pairs obtained in that paper could be leveraged into a scheme for quantum key distribution (QKD) that is secure in the device-independent (DI) model of security. We believe it should be possible to use the Pauli braiding test to develop a DIQKD protocol in which the interaction with the devices can be executed in parallel, but we leave this possibility for future work.

3. The energy test can be viewed as a “device independent property test” for any property of a quantum state that can be suitably expressed as a Hamiltonian. Are there other device-independent property tests that can be formulated in our framework? It would be interesting to see which results from the survey of Montanaro and de Wolf on quantum property testing \cite{MdW13} can be generalized to the device-independent setting.

Organization of the paper. In Section 2 we introduce some notation used throughout as well as basic definitions of stabilizer codes and local Hamiltonians. In Section 3 we establish an important technical component of our results, the linearity test and its quantum analysis. We expand this into a two-prover self-test for the Pauli group on \( n \)-qubits in Section 4, which forms the basis for our
main result. In Section 5 we extend this test to handle more than two provers and show how it can be combined with an energy measurement test to devise a game for the local Hamiltonian problem. In Section 6 we discuss the application of our protocol to delegated computation.

2 Preliminaries

We assume basic familiarity with quantum information but give all required definitions. We refer to the standard textbook [NC01] for additional background material.

2.1 Quantum states and measurements

A $n$-qubit pure quantum state is represented by a unit vector $|\psi\rangle \in \mathbb{C}^2 \otimes \cdots \otimes \mathbb{C}^2 = (\mathbb{C}^2)^{\otimes n} \approx \mathbb{C}^{2^n}$, where the ket notation $|\cdot\rangle$ is used to signify a column vector. A bra $\langle \cdot |$ is used for the conjugate-transpose $\langle \psi | = |\psi^\dagger\rangle$, which is a row vector. We use $\|\psi\|^2 = |\langle \psi | \psi \rangle|$ to denote the Euclidean norm, where $\langle \psi | \phi \rangle$ is the skew-Hermitian inner product between vectors $|\phi\rangle$ and $|\psi\rangle$. A $n$-qubit mixed state is represented by a density matrix, a positive semi-definite matrix $\rho \in \mathbb{C}^{2^n} \times \mathbb{C}^{2^n}$ of trace 1. The density matrix associated to $|\psi\rangle$ is the rank-1 projection $|\psi\rangle \langle \psi |$. We use $D(H)$ to denote the set of all density matrices on $H$.

For a matrix $X$, $\|X\|$ will refer to the operator norm, the largest singular value. When the Hilbert space can be decomposed as $H = H_A \otimes H_B$ for some $H_A$ and $H_B$, and $X$ is an operator on $H_A$, we often write $X$ as well for the operator $X \otimes \mathbb{1}_{H_B}$ on $H$. It will always be clear from context which space an operator acts on. All Hilbert spaces considered in the paper are finite dimensional.

We use $\text{Pos}(H)$ to denote the set of positive semidefinite operators on $H$. A $n$-qubit measurement (also called POVM, for projective operator-valued measurement) with $k$ outcomes is specified by $k$ positive matrices $M = \{M_1, \ldots, M_k\} \subseteq \text{Pos}(\mathbb{C}^{2^n})$ such that $\sum_i M_i = \mathbb{1}$. The measurement is projective if each $M_i$ is a projector, i.e. $M_i^2 = M_i$. The probability of obtaining the $i$-th outcome when measuring state $\rho$ with $M$ is $\text{Tr}(M_i \rho)$. By Naimark’s dilation theorem, any POVM can be simulated by a projective measurement acting on an enlarged state; that is, for every POVM $M = \{M_i\}_i$ acting on state $|\psi\rangle \in H$ there exists a projective measurement $M' = \{P_i\}_i$ and a state $|\psi\rangle \otimes |\phi\rangle \in H \otimes H_{\text{ancilla}}$ with the same outcome probabilities as $M$. Moreover, the post-measurement state after performing $M$ is the same as the reduced post-measurement state obtained after performing $M'$ and tracing out the ancilla subsystem $H_{\text{ancilla}}$.

An $n$-qubit observable is a Hermitian matrix $O \in \mathbb{C}^{2^n} \times \mathbb{C}^{2^n}$ that squares to identity. We use $\text{Obs}(H)$ to denote the set of observables acting on $H$. $O \in \text{Obs}(H)$ is diagonalizable with eigenvalues $\pm 1$, $O = P_+ - P_-$, and $P = \{P_+, P_-\}$ is a projective measurement. For any state $\rho$, $\text{Tr}(O \rho)$ is the expectation of the $\pm 1$ outcome obtained when measuring $\rho$ with $P$. If $\rho = |\psi\rangle \langle \psi |$ we abbreviate this quantity, $\text{Tr}(O \rho) = \text{Tr}(P_+ \rho) - \text{Tr}(P_- \rho) = \langle \psi | O | \psi \rangle$ as $\langle \psi | O | \psi \rangle$.

A convenient orthogonal basis for the real vector space of $n$-qubit observables is given by the set $\{I, \sigma_X, \sigma_Y, \sigma_Z\}^{\otimes n}$, where $\{I, \sigma_X, \sigma_Y, \sigma_Z\}$ are the four single-qubit Pauli observables

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \sigma_X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_Y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$  

We call the eigenbasis of $\sigma_X$ (resp. $\sigma_Z$) the $X$-basis (resp. $Z$-basis). We often consider operators that are tensor products of just $I$ and $\sigma_X$, or just $I$ and $\sigma_Z$. We denote these by $\sigma_X(a), \sigma_Z(b)$, where

</table>

The strings \(a, b \in \{0, 1\}^n\) indicate which qubits to apply the \(\sigma_X\) or \(\sigma_Z\) operators to: a 0 in position \(i\) indicates an \(I\) on qubit \(i\), and a 1 indicates an \(\sigma_X\) or \(\sigma_Z\). We denote by

\[
|\text{EPR}\rangle = \frac{1}{\sqrt{2}} |0\rangle |0\rangle + \frac{1}{\sqrt{2}} |1\rangle |1\rangle
\]

the unique state stabilized by both \(\sigma_X \otimes \sigma_X\) and \(\sigma_Z \otimes \sigma_Z\).

### 2.2 Stabilizer codes

Stabilizer codes are the quantum analogue of linear codes. For an introduction to the theory of stabilizer codes we refer to [Got97]. We will only use very elementary properties of such codes.

The codes we consider are Calderbank-Shor-Steane (CSS) codes [CS96, Ste96]. For an \(r\)-qubit code the codespace, the vector space of all valid codewords, is the subspace of \((\mathbb{C}^2)^\otimes r\) that is the simultaneous +1 eigenspace of a set \(\{S_1, \ldots, S_k\}\) of \(r\)-qubit pairwise commuting Pauli observables called the stabilizers of the code. The stabilizers form a group under multiplication. Unitary operations, such as a Pauli \(X\) or \(Z\) operators, on the logical qubit are implemented on the codespace by logical operators \(X_{\text{logical}}\) and \(Z_{\text{logical}}\). The smallest CSS code is Steane’s 7-qubit code [Ste96]. Table 1 lists a set of stabilizers that generate the stabilizer group of the code.

Every CSS code satisfies certain properties which will be useful for us. Firstly, both the stabilizer generators and the logical operators can be written as tensor products of only \(I\), \(\sigma_X\), and \(\sigma_Z\) operators — there are no \(\sigma_Y\). This simplifies our protocol, allowing us to consider only two distinct basis settings. Secondly, every CSS code has the following symmetry: for every index \(i \in [r]\) there exists stabilizers \(S_X, S_Z\) such that \(S_X\) is a tensor product of only \(\sigma_X\) and \(I\) operators and has an \(\sigma_X\) at position \(i\), and \(S_Z\) is equal to \(S_X\) with all \(\sigma_X\) operators replaced by \(\sigma_Z\) operators.

These properties imply the following simple observation, which will be important for us. For every Pauli operator \(P \in \{I, \sigma_X, \sigma_Z\}\) acting on the \(i\)-th qubit of the code there is a tensor product \(\hat{P}\) of Paulis acting on the remaining \((r - 1)\) qubits such that \(P \otimes \hat{P}\) is a stabilizer operator on the whole state, and moreover each term in the tensor product is either identity or \(\hat{P}\). Indeed, the choice of \(\hat{P}\) is not unique. Henceforth, we use the notion \(\hat{P}\) to denote any such operator, unless otherwise specified.
2.3 Local Hamiltonians

A $n$-qubit local Hamiltonian is a Hermitian, positive semidefinite operator $H$ on $(\mathbb{C}^2)^\otimes n$ that can be decomposed as a sum $H = \sum_{i=1}^{m} H_i$ with each $H_i$ is local, i.e. $H_i$ can be written as $H_i = I \otimes \cdots \otimes I \otimes h_i \otimes I \otimes \cdots \otimes I$, where $h_i$ is a Hermitian operator on $(\mathbb{C}^2)^\otimes k$ with norm (largest singular value) at most 1. The smallest $k$ for which $H$ admits such a decomposition is called the locality of $H$. The terms are normalized such that $\|H_i\| \leq 1$ for all $i$. A family of Hamiltonians $\{H_i\}$ acting on increasing numbers of qubits is called local if all $H_i$ are $k$-local for some $k$ independent of $n$ (for us $k$ will always be 2).

The local Hamiltonian problem is the prototypical QMA-complete problem, as 3SAT is for NP.

**Definition 5.** Let $k \geq 2$ be an integer. The $k$-local Hamiltonian problem is to decide, given a family of $k$-local Hamiltonians $\{H_n\}_{n \in \mathbb{N}}$ such that $H_n$ acts on $n$ qubits, and functions $a, b : \mathbb{N} \to (0, 1)$ such that $b - a = \Omega(\text{poly}^{-1}(n))$, if the smallest eigenvalue of $H_n$ is less than $a(n)$ or greater than $b(n)$.

Here we restrict our attention to Hamiltonians

$$H = \frac{1}{m} \sum_{i=1}^{m} H_i,$$

for which each term $H_i$ can be written as a linear combination of tensor products of Pauli $I$, $\sigma_X$ and $\sigma_Z$ observables only. Such Hamiltonians are known to be QMA complete for some constant $k$ (see Lemma 22 of [Ji16a] for a proof).

2.4 State-dependent distance measure and approximations

We make extensive use of a state-dependent distance between measurements that has been frequently used in the context of entangled-prover interactive proof systems (see e.g. [IV12, Ji16a]). For $\rho$ a positive semidefinite matrix and $X$ any linear operator define

$$\text{Tr}_\rho(X) = \text{Tr}(\rho X).$$

For any two operators $S, T$, define the state-dependent distance between $S$ an $T$ on a $\rho$ as

$$d_\rho(S, T) := \sqrt{\text{Tr}_\rho ((S - T)^\dagger (S - T))}.$$  

Based on the state-dependent distance we define a distance between POVMs, given by summing the state-dependent distance between the square roots of the POVM elements. Let $\{M^a\}$ and $\{N^a\}$ be two POVMs with the same number of outcomes, indexed by $a$, and let $|\psi\rangle$ be a quantum state. Then the state-dependent distance between the POVMs $M$ and $N$ on $\rho$ is denoted as $d_\rho(\sqrt{M}, \sqrt{N})$ and defined as

$$d_\rho(\sqrt{M}, \sqrt{N}) = \left( \sum_a d_\rho(\sqrt{M^a}, \sqrt{N^a})^2 \right)^{1/2}.$$ 

While this notation is ambiguous (since the sum over outcomes is not explicitly indicated), context will always make it clear which notion of $d_\rho$ is intended. We will also drop the square roots in the case of POVMs that are projective measurements.
To simplify the notation, let $A^a = \sqrt{M^a}$ and $B^a = \sqrt{N^a}$. Then this distance can be rewritten as:

$$d_\rho(\sqrt{M}, \sqrt{N})^2 = \sum_a \text{Tr}_\rho \left( (A^a - B^a)^2 \rho \right)$$

$$= 2 - \sum_a \text{Re} \text{Tr}_\rho \left( A^a B^a \right),$$

(3)

where we used the fact that $A^a$ and $B^a$ are Hermitian and their squares sum to identity. If we specialize to the case of projective measurements with binary outcomes, we get the following relations (here $A = A^1 - A^{-1}$ and $B = B^1 - B^{-1}$ are the observables associated to the measurements):

$$d_\rho(\sqrt{M}, \sqrt{N})^2 = 2 - \text{Tr}_\rho \left( A^1 B^1 + A^{-1} B^{-1} + B^1 A^1 + B^{-1} A^{-1} \right)$$

$$= 2 - \frac{1}{4} \text{Tr}_\rho \left( (\mathbb{I} + A)(\mathbb{I} + B) + (\mathbb{I} - A)(\mathbb{I} - B) + (\mathbb{I} + B)(\mathbb{I} + A) + (\mathbb{I} - B)(\mathbb{I} - A) \right) \langle \psi \rangle$$

$$= 2 - \frac{1}{4} \text{Tr}_\rho \left( 4 \mathbb{I} + 2AB + 2BA \right)$$

$$= 1 - \frac{1}{2} \text{Tr}_\rho \left( AB + BA \right)$$

$$= \frac{1}{2} \text{Tr}_\rho \left( (A - B)^2 \right)$$

$$= d_\rho(A, B)^2.$$ 

(4)

This distance measure has the following useful property:

**Lemma 6.** Let $\rho$ be positive semidefinite, $C$ be a linear operator such that $\|CC^\dagger\| \leq K$ and $S, T$ linear operators. Then

$$\left| \text{Tr}_\rho(CS) - \text{Tr}_\rho(CT) \right| \leq \sqrt{2K} d_\rho(S, T).$$

Likewise, if $\{C_a\}$ a family of operators such that $\| \sum_a C_a C_a^\dagger \| \leq K$ and $\{M^a\}$ and $\{N^a\}$ POVMs. Then

$$\left| \sum_a \text{Tr}_\rho \left( C_a \sqrt{M^a} \right) - \sum_a \text{Tr}_\rho \left( C_a \sqrt{N^a} \right) \right| \leq \sqrt{K} d_\rho(\sqrt{M}, \sqrt{N}).$$

**Proof.** The proof of both results is identical, and uses the Cauchy-Schwarz inequality; we show only the proof of the second. Let $A^a = \sqrt{M^a}$ and $B^a = \sqrt{N^a}$. Applying the Cauchy-Schwarz inequality,

$$\left| \sum_a \text{Tr}_\rho \left( C_a (A^a - B^a) \right) \right| \leq \text{Tr}_\rho \left( \sum_a C_a C_a^\dagger \right)^{1/2} \text{Tr}_\rho \left( \sum_a (A^a - B^a)^2 \right)^{1/2}$$

$$\leq \sqrt{K} d_\rho(\sqrt{M}, \sqrt{N}),$$

as claimed. \qed

A second measure of proximity that is often convenient is the **consistency**. As before, let $\{M^a\}$ and $\{N^a\}$ be POVMs with the same number of outcomes. Then their consistency is defined as

$$C_\rho(M, N) = \text{Re} \left( \sum_a \text{Tr}_\rho \left( M^a N^a \right) \right),$$
so that by (3) we have
\[ d_\rho(\sqrt{M}, \sqrt{N})^2 = 2 - 2 C_\rho(\sqrt{M}, \sqrt{N}). \]  

(5)

For collections of binary observables \{A(a)\} and \{B(a)\} we use
\[ C_\rho(A, B) = \sum_a \text{Re} \left( \sum_{c \in \{0, 1\}} \frac{1}{4} \text{Tr}_\rho \left( (\mathbb{I} + (-1)^c A(a)) (\mathbb{I} + (-1)^c B(a)) \right) \right) \]

\[ = \frac{1}{2} \text{Re} \left( 1 + \sum_a \text{Tr}_\rho \left( A(a) B(a) \right) \right). \]

A useful property of the consistency is that if \( M \) and \( N \) are POVMs acting on two separate subsystems of \( \rho \), applying Naimark dilation to each of them results in projective measurements \( M' \) and \( N' \) and a state \( \rho' \) such that \( C_\rho(M, N) = C_\rho'(M', N') \).

Given two observables \( A \) and \( B \), the product \( AB \) is an observable if and only if \( A \) and \( B \) commute. The following lemma shows how to define a “product” observable \( C \) when \( A \) and \( B \) commute only approximately in state-dependent distance, such that the action of \( C \) on the state is close to \( AB \) (and \( BA \)).

**Lemma 7.** Let \( \rho \) be a density matrix and \( A, B \) observables such that \( d_\rho(AB, BA) \leq \delta \) for some \( \delta \geq 0 \). Let \( C \) be the observable defined by
\[ C = \frac{AB + BA}{|AB + BA|}, \]
where we use the convention that \( M/|M| \) is defined as the identity on the kernel of \( M \). Then
\[ \max \left\{ d_\rho(C, AB), d_\rho(C, BA) \right\} \leq \frac{\sqrt{2}}{2} \delta. \]

**Proof.** It is clear from the definition that \( C \) is Hermitian and an observable (i.e. all its eigenvalues are \( \pm 1 \)). Evaluate
\[ d_\rho(AB, C)^2 = 2 - \text{Tr}_\rho \left( \frac{AB + BA}{|AB + BA|} AB + BA \frac{AB + BA}{|AB + BA|} \right). \]

Notice that \( AB \) and \( BA \) both commute with \( (AB + BA) \) and hence with \( (AB + BA)/|AB + BA| \). Thus the above expression simplifies to
\[ d_\rho(AB, C)^2 = 2 - \text{Tr}_\rho \left( \frac{(AB + BA)^2}{|AB + BA|} \right) \]
\[ \leq 2 - \text{Tr}_\rho |AB + BA| \]
\[ \leq 2 - \frac{1}{2} \text{Tr}_\rho ((AB + BA)^2) \]
\[ = 2 - \frac{1}{2} \text{Tr}_\rho (2\mathbb{I} + AB AB + BAB A). \]

From the assumption, \( d_\rho(AB, BA)^2 = \text{Tr}_\rho (2\mathbb{I} - AB AB - BAB A) \leq \delta^2 \). Substituting in the above, we get \( d_\rho(AB, C)^2 \leq \delta^2/2 \), as desired. \( \square \)
Our calculations will often require estimates of the form $E_x d_p(A_x, B_x)^2 = O(\epsilon)$ where the expectation is taken according to some distribution on $x$ (always over a finite set) that will be clear from context. We introduce the following notation to represent the same estimate:

$$A_x|\psi\rangle \approx_x B_x|\psi\rangle.$$ 

Here $|\psi\rangle$ can be understood as any purification of $\rho$, with the usual convention that operators are extended to act as identity on spaces on which they are not defined. If the symbol $x$ is omitted then the distribution should be clear from context. If it needs to be specified we may write e.g. $A_x|\psi\rangle \approx_x^{x_1=0} B_x|\psi\rangle$, meaning that the distribution on $x$ is the one clear from context (typically, uniform on $\{0,1\}^n$), conditioned on the first bit of $x$ being a 0. Although the notation can be ambiguous when taken out of context we hope that it will help make some of the more cumbersome derivations more transparent.

2.5 Nonlocal games

In the paper we formulate a number of tests meant to be executed between a verifier and $r$ players (sometimes also called provers), for $r \geq 1$ an integer. These tests all take the form of a classical one-round interaction: the verifier samples an $r$-tuple of questions and sends one question to each player; the players each provide an answer to the verifier, who decides to accept or reject. If the verifier accepts the players are said to win the game.

We call a tuple $(N, |\psi\rangle)$, where $|\psi\rangle \in \mathcal{H}_1 \otimes \cdots \otimes \mathcal{H}_r$ is an entangled state on the joint space of all $r$ players, and $N$ a collection of POVM for each player and possible question to the player, a strategy for the players in $G$. Note that we may always assume $|\psi\rangle$ is a pure state and all POVM are projective.

Given a game $G$ we denote by $\omega^*(G)$ the highest probability of winning that can be achieved by $r$ players sharing quantum entanglement. For a more thorough introduction to nonlocal games in a similar framework as used here we refer to e.g. [116a].

One of our tests uses nonlocal games as a means to enforce anticommutation relations between a player’s observables. Towards this we introduce the following definition.

Definition 8 (Anticommutation game). Let $\omega_{ac}^* \in (0,1]$ and $\delta : [0,1] \to [0,1]$ a continuous function such that $\delta(0) = 0$. A two-player game $G$ is called a $(\omega_{ac}^*, \delta)$ anticommutation game if $\omega^*(G) \geq \omega_{ac}^*$ and moreover there exist questions $q_X, q_Z$ (called special questions) to the second player and the $\{\pm 1\}$-valued functions $f_X, f_Z$ defined on the player’s set of possible answers to questions $q_X, q_Z$ respectively such that the following two properties hold:

1. Completeness: There exists a strategy using the state $|\text{EPR}\rangle_{AB}^{\otimes m}$ for some $m \geq 1$ and projective measurements that achieves the optimal success probability $\omega_{ac}^*$, and is such that measurement operators $\{A^a_q\} \in \text{Pos}(\mathcal{H}_A)$ for the second player satisfy $\sum_a f_X(a) A^a_{X} = \sigma_X \otimes \mathbb{I}$ and $\sum_a f_Z(a) A^a_{Z} = \sigma_Z \otimes \mathbb{I}$, where $\sigma_X$ and $\sigma_Z$ act on the first EPR pair and the identity on the remaining EPR pairs. Moreover, for every question $q$ received by the second player and answer $a$, the projector $A^a_q$ can be written as $A^a_q = \sum_j \Pi_j$, where each $\Pi_j$ is the projector onto an eigenspace of a tensor product of $\sigma_X, \sigma_Z$ and $\mathbb{I}^2$. We call such a strategy an honest strategy for $G$.\footnote{This seemingly ad-hoc condition is needed for the use of the anticommutation game in the Hamiltonian self-test described in Section 5 but not in the Pauli braiding test from Section 4.}
2. Soundness: Let a projective strategy for the players in $G$ be given such that the strategy uses entangled state $|\psi\rangle \in \mathcal{H}_A \otimes \mathcal{H}_B$ and measurement operators $\{A^a\}_a \in \text{Pos}(\mathcal{H}_A)$ for the second player. Then for any $\epsilon > 0$, provided the strategy has success probability at least $\omega_{\text{ac}}^e - \epsilon$ in $G$, there exists isometries $U : \mathcal{H}_A \rightarrow \mathbb{C}^2 \otimes \mathcal{H}_{A'}$ and $V : \mathcal{H}_B \rightarrow \mathbb{C}^2 \otimes \mathcal{H}_{B'}$ and a state $|\psi'\rangle \in \mathcal{H}_{A'} \otimes \mathcal{H}_{B'}$ such that

$$X = \sum_a f_X(a)A^a_{qX} \quad \text{and} \quad Z = \sum_a f_Z(a)A^a_{qZ}$$

then

$$\|U \otimes V|\psi\rangle - |\text{EPR}\rangle \otimes |\psi'\rangle\| \leq \delta \quad \text{and} \quad \max \left\{ d_\rho(X, U^\dagger (\sigma_X \otimes I_{A'})U), d_\rho(Z, V^\dagger (\sigma_Z \otimes I_{B'})V) \right\} \leq \delta.$$

The CHSH game [CHSH69] and the Mermin-Peres Magic Square game [Mer90, Per90] are both known to be anti-commutation games. For the former, see e.g. [MYS12] and for the latter, [WBMS16, CN16]. The advantage of the CHSH game is that there is an optimal strategy which only requires a single EPR pair of entanglement. The Magic Square has the advantage of having value 1, but an optimal strategy requires two EPR pairs.

**Lemma 9.** The CHSH game is a $(\cos^2 2\pi/8, O(\sqrt{\epsilon}))$ anti-commutation game. The Magic Square game is a $(1, O(\sqrt{\epsilon}))$ anti-commutation game.

## 3 The linearity test

We state and analyze a variant of the classic 3-query linearity test of Blum, Luby, and Rubinfeld [BLR93] (BLR) that can be played with two entangled players. The two-player test is based on the idea of oracularization with a dummy question introduced in [IKM09]. Our analysis builds on [LV12], who analyze a 3-player variant. Their proof is an extension of the Fourier-analytic proof due to Håstad to the matrix-value measuring valued setting. We analyze the two-player variant using similar techniques.

We note that the use of two players, rather than three as in the original test, is essential for our applications to self-testing. Ultimately we will require the provers to succeed in a linearity test performed in either of two mutually incompatible bases (e.g. the $X$ and $Z$ bases). Two provers can achieve this by sharing a maximally entangled state, but there is no tripartite state that would allow three entangled provers to obtain consistent answers whenever they measure their share of the state in either the $X$ or the $Z$ basis. (Formulated differently, $\sigma_X \otimes \sigma_X$ and $\sigma_Z \otimes \sigma_Z$ share a common +1 eigenvector, the EPR pair; $\sigma_X \otimes \sigma_X \otimes \sigma_X$ and $\sigma_Z \otimes \sigma_Z \otimes \sigma_Z$ do not. This is a manifestation of entanglement monogamy.)

We show the result in two steps. First we show that any set of quantum observables satisfying linearity relations approximately in expectation can be “rounded” to a nearby set of observables satisfying these relations exactly.

**Theorem 10.** Suppose there exist observables $\{A(a)\}_{a \in \{0, 1\}^n}$ in $\text{Obs}(\mathcal{H})$ acting on a state $\rho \in D(\mathcal{H})$ such that

$$E_{a,b} \text{Tr}_\rho (A(a)A(b)A(a + b)) \geq 1 - \delta.$$  

Then there exists an extended state $\rho' = \rho \otimes |\text{anc}\rangle \langle \text{anc}| \in D(\mathcal{H} \otimes \mathcal{H}')$ and observables $\{A(a)\}$ in $\text{Obs}(\mathcal{H} \otimes \mathcal{H}')$ such that

$$A(a)A(b) = A(a + b) \quad \forall a, b \in \{0, 1\}^n \quad \text{and} \quad E_{a} d_{\rho'}(A(a), A(a))^2 \leq \delta.$$
Here, and throughout this paper, the notation $a + b$ denotes the bitwise XOR of $a$ and $b$, i.e. the sum of $a$ and $b$ viewed as elements of the additive group $\mathbb{Z}_2^n$. We call observables $\{A(a)\}$ satisfying the first set of relations in (8) exactly linear.

**Proof.** For every $u \in \{0,1\}^n$ consider the Fourier transform $\hat{A}^u = E_a(-1)^{a\cdot u}A(a)$. Define measurement operators $B^u = (\hat{A}^u)^2$. By Parseval’s identity, these operators form a POVM. Using Naimark’s theorem there exists an ancilla space $H', |\text{anc}\rangle\langle\text{anc}| \in \mathcal{D}(H')$, and a projective measurement $\{C^u\}$ on $H \otimes H'$ that simulates $\{B^u\}$. Introduce observables $A(a) = \sum_u (-1)^{u\cdot a}C^u$.

From the orthogonality of the projectors $C^u$ it follows that $A(a)A(b) = A(a + b)$. Write

$$E_a C'_{\rho'}(A(a), A(a)) = \frac{1}{2} + \frac{1}{2} E_a \text{Re} \text{Tr}_{\rho'}(A(a)A(a))$$

$$= \frac{1}{2} + \frac{1}{2} E_a \text{Re} \left( \sum_u \text{Tr}_{\rho'}((-1)^{u\cdot a}A(a)(\hat{A}^u)^2) \right)$$

$$= \frac{1}{2} + \frac{1}{2} \sum_u \text{Tr}_{\rho'}((\hat{A}^u)^3).$$

To conclude, note that $\sum_u \text{Tr}_{\rho'}((\hat{A}^u)^3) = E_{ab} \text{Tr}_{\rho'}(A(a)A(b)A(a + b))$, and use the assumption made in the theorem and the relation between $C'_{\rho'}$ and $d^2_{\rho'}$. \hfill $\square$

Next we exhibit a two-player game such that any strategy which succeeds with probability at least $1 - \epsilon$ in the game must satisfy the assumption (7) of Theorem 10 for some $\delta = O(\sqrt{\epsilon})$.

The verifier performs the following one-round interaction with two players. He starts by choosing one of the players at random and labels her Alice; the other player is labeled Bob. In each test each player is sent a pair of $n$-bit strings. The $n$-bit strings are always assumed to be sent in lexicographic order.

1. Choose two strings $a, b \in \{0,1\}^n$ uniformly at random. Send $(a, b)$ to Alice.

2. Let $c$ be with equal probability either $a$, $b$, or $a + b$, and let $c' \in \{0,1\}^n$ be chosen uniformly at random. Send $(c, c')$ to Bob.

3. The players reply with $\alpha, \beta \in \{\pm 1\}$ and $\gamma, \gamma' \in \{\pm 1\}$ respectively. Depending on the value of $c$ the verifier performs one of the following two tests:

   (a) **Consistency test:** if $c = a$ (resp. $b$), accept if and only if both players return the same value as their answer to that question: $\gamma = \alpha$ (resp. $\gamma = \beta$).

   (b) **Linearity test:** if $c = a + b$, accept if and only if $\gamma = \alpha \beta$.

---

Figure 1: The two-player linearity test
Theorem 11. Suppose two players Alice and Bob succeed in the linearity test of Figure 1 with probability at least $1 - \epsilon$, using a shared state $|\psi\rangle_{AB} \in \mathcal{H}_A \otimes \mathcal{H}_B$ and projective measurements $\{M_{a,b}^{\alpha,\beta}\}_{a,b} \in \text{Pos}(\mathcal{H}_A)$ and $\{N_{a,b}^{\alpha,\beta}\}_{a,b} \in \text{Pos}(\mathcal{H}_B)$ respectively. Consider the POVM $\{\tilde{M}_a^{\alpha}\}_{a}$ whose elements are given by $\tilde{M}_a^{\alpha} := E_b \sum_{\beta} M_{a,b}^{\alpha,\beta}$, and let $\{A_{a}^{\alpha}\}_{a} \in \text{Pos}(\mathcal{H}_A \otimes \mathcal{H}_A')$ be the projective measurement obtained by Naimark dilation of $\tilde{M}$.

Then the observables $A(a) := A_{a}^{0} - A_{a}^{1}$ satisfy

$$E_{a,b} \text{Tr}_{\rho'}(A(a)A(b)A(a + b)) = 1 - O(\sqrt{\epsilon}),$$

where $\rho' = |\psi\rangle\langle\psi| \otimes |\text{anc}\rangle\langle\text{anc}|_{\mathcal{H}_A'}$.

Proof of Theorem 11. Introduce the following conditional measurement operator on $\mathcal{H}_B$,

$$N_{a|ab}^{\alpha} = \sum_{\beta} N_{a,b}^{\alpha,\beta}.$$ 

Note that for every $a$, $b$, and $\alpha$, $N_{a|ab}^{\alpha}$ is a projector since we assumed each $M_{a,b}^{\alpha,\beta}$ is as well. Suppose that the players’ acceptance probability conditioned on the verifier performing the consistency part of the test (i.e. $c = a$ or $c = b$) is $1 - \epsilon_c$, while conditioned on the verifier performing the linearity part of the test (i.e. $c = a + b$) it is $1 - \epsilon_l$, so that $\epsilon = 2\epsilon_c / 3 + \epsilon_l / 3$. Let $\rho = |\psi\rangle\langle\psi|_{AB}$. By definition of the consistency test,

$$1 - \epsilon_c = E_{a,b} C_\rho(M_a, N_{a|ab}).$$

Using Naimark’s dilation theorem there is an ancilla space $\mathcal{H}_A$ and $|\text{anc}\rangle\langle\text{anc}| \in D(\mathcal{H}_A')$ such that the POVM $\{\tilde{M}_a^{\alpha}\}$ acting on $\mathcal{H}_A$ can be simulated by a projective measurement $\{A_a^{\alpha}\}$ acting on $\rho' = \rho \otimes |\text{anc}\rangle\langle\text{anc}|_{\mathcal{H}_A'}$. Let $d(a|ab) = d_{\rho'}(A_a, N_{a|ab})$, so that by Jensen’s inequality, (5) and (9),

$$E_{a,b} d(a|ab) \leq \sqrt{E_{a,b} d(a|ab)^2} = O\left(\sqrt{E_{a,b} C_\rho(M_a, N_{a|ab})}\right) = O(\sqrt{\epsilon_c}).$$

Now compute

$$E_{a,b} \text{Tr}_{\rho'}(A(a)A(b)A(a + b)) = E_{a,b} \sum_{\alpha,\beta} \text{Tr}_{\rho'}(A_a^{\alpha} A_{b}^{\beta} A_{a+b}^{\alpha,\beta} - A_a^{\alpha} A_{b}^{\beta} A_{-a-b}^{\alpha,\beta})$$

$$= 2 E_{a,b} \sum_{\alpha,\beta} \text{Tr}_{\rho'}(A_a^{\alpha} A_{b}^{\beta} A_{a+b}^{\alpha,\beta}) - 1$$

$$\geq 2 E_{a,b} \left(\sum_{\alpha,\beta} \text{Tr}_{\rho'}(A_a^{\alpha} A_{b}^{\beta} N_{a|ab}^{\alpha} N_{b|ab}^{\beta}) - O(d(a|ab) + d(b|ab))\right) - 1$$

$$= 1 - O(\epsilon_l + \sqrt{\epsilon_c}),$$

where the inequality uses Lemma 6 and the last line is by (10) and, by definition of the linearity test,

$$1 - \epsilon_l = E_{a,b} \sum_{\alpha,\beta} \text{Tr}_{\rho}(\tilde{M}_{a+b}^{(\alpha\beta)} N_{ab}^{\alpha\beta}).$$
$$= E_{ab} \sum_{\alpha, \beta} \text{Tr} \rho \left( \tilde{M}^{(\alpha\beta)}_{a+b} N^{\alpha}_{a|b} N^{\beta}_{b|a} \right),$$

since the POVM elements $N^{\alpha\beta}_{a|b}$ are projectors. \hfill \Box

4 The Pauli braiding test

In this section we combine the linearity test with an anticommutation test based on any anticommutation game $G_{ac}$ satisfying Definition 8 to devise a two-player test for which the honest strategy consists of applying tensor products of single-qubit observables in the set $\{\sigma_X(a)\sigma_Z(b), a, b \in \{0, 1\}\}$. We show that for any strategy with near-optimal success probability there exists a (local) isometry under which the players’ observables are close (in the state-dependent distance) on average to operators satisfying the Pauli commutation and anti-commutation (“braiding”) relations perfectly.

4.1 The protocol

Let $G_{ac}$ be a two-player anticommutation game, with special questions $q_X, q_Z$. The verifier performs the following one-round interaction with two players. He starts by choosing one of the players at random and labels them Alice; the other player is labeled Bob. In each test a player will be sent a label and a pair of $n$-bit strings. The $n$-bit strings are always assumed to be sent in lexicographic order.

1. **Linearity test:** The verifier chooses a basis setting $W \in \{X, Z\}$ and sends it to both players. He executes the two-player linearity test with the players.

2. **Anticommutation test:** The verifier chooses two strings $a, b \in \{0, 1\}^n$ such that $a \cdot b = 1 \mod 2$ uniformly at random, and sends $(a, b)$ to both players. He executes the game $G_{ac}$ with the players and accepts if and only if they succeed.

3. **Consistency test:** The verifier chooses two strings $a, b \in \{0, 1\}^n$ such that $a \cdot b = 1 \mod 2$ uniformly at random, and a basis setting $W \in \{X, Z\}$. He sends $(W, a, b)$ to Alice. With probability 1/2 each,

   - He samples a question $q$ from the second player’s distribution in $G_{ac}$ and sends $(q, a, b)$ to Bob. If $q = q_X$ (resp. $q = q_Z$) he accepts if and only if Alice’s answer associated to $a$ (resp. $b$) equals $f_W(\alpha)$, where $\alpha$ is Bob’s answer and $f_W$ the function from Definition 8. Otherwise, he accepts automatically.

   - He selects a uniformly random $c \in \{0, 1\}^n$ and sends $(N, a, c)$ to Bob. He accepts if and only if the product of Alice and Bob’s answers associated to the query string $a$ is +1.

Figure 2: The two-player Pauli braiding test
The protocol for the Pauli braiding test is described in Figure 2. In the protocol there are several possible types of queries that each player may receive. For convenience we give them the following names:

1. A $W$-query, represented by $(W, a, b)$, where $W \in \{X, Z\}$ and $a, b$ are uniformly random strings in $\{0, 1\}^n$. The expected answer is two bits $\alpha, \beta \in \{-1, 1\}$.

2. A $G$-query, represented by $(q, a, b)$ where $q$ is a question in $G_{ac}$ and $a, b$ are uniformly random strings in $\{0, 1\}^n$. The expected answer is a single value $\alpha$ taken from the answer alphabet in $G$.

To each query is associated an intended behavior of the player, which is specified as part of the honest strategy given in the following definition.

**Definition 12.** The honest strategy for the two players in the Pauli braiding test consists of the following. Let $U, V$ be unitaries to an optimal strategy in $G_{ac}$ as in Definition 8 and recall that by the completeness property this strategy can be implemented by sharing $m$ EPR pairs of entanglement.

The players share the state $|\psi\rangle_{AB} = |\text{EPR}\rangle^n_{AB} \otimes |\text{EPR}\rangle^{(m-1)}_{A'B'}$. Upon receiving a query, a player performs the following depending on the type of the query:

- **$W$-query** $(W, a, b)$, for $W \in \{X, Z\}$: measure the compatible observables $\sigma_W(a)$ and $\sigma_W(b)$ on its share of $|\text{EPR}\rangle^n_{AB}$ and return the two outcomes.

- **$G$-query** $(q, a, b)$. Suppose the query is sent to Alice, the case of Bob being treated symmetrically. Let $W_{a,b}: \mathbb{C}^{2^n} \to \mathbb{C}^{2^n}$ be a unitary such that $W_{a,b}\sigma_X(a)W_{a,b}^\dagger = I_{\mathbb{C}^{2^{n-1}}} \otimes \sigma_X$ and $W_{a,b}\sigma_Z(b)W_{a,b}^\dagger = I_{\mathbb{C}^{2^{n-1}}} \otimes \sigma_Z$. (Such a $W_{a,b}$ exists and can be agreed upon by the players since in a $G$-query it is always the case that $a \cdot b = 1 \mod 2$, and both players are sent the same pair $(a, b)$.) Let $\{A^q_{ab}\}_{\alpha}$ be the projective measurement on $\mathbb{C}^2 \otimes \mathcal{H}_A$ associated with the first player in a honest strategy in $G$. Then Alice performs the projective measurement

$$\{(W_{a,b}^\dagger \otimes I_A')(I_{\mathbb{C}^{2^{n-1}}} \otimes A^q_{ab})(W_{a,b} \otimes I_A')\}_{\alpha}$$

and returns the outcome.

Having defined the honest strategy for the players we introduce some notation associated with arbitrary strategies in the protocol. We specify a strategy using the shorthand $(N, |\psi\rangle_{AB})$. Here $|\psi\rangle_{AB}$ denotes the bipartite state shared by the players, and $N$ the collection of POVM that the players apply in response to the different types of queries they can be asked. Using Naimark’s theorem we may assume without loss of generality that $|\psi\rangle_{AB}$ is a pure state and each player’s POVM is projective.

Given a query $(X, a, b)$ (resp. $(Z, a, b)$), we denote by $\{N^{\alpha\beta}_{ab}\}_{\alpha, \beta}$ (resp. $\{M^{\alpha\beta}_{ab}\}_{\alpha, \beta}$) the two-outcome projective measurement that is applied by a given player. Since the protocol treats the players symmetrically we may assume that these operators are the same for both Alice and Bob (see e.g. [Vid13] Lemma 2.5). By taking appropriate marginals over the answers we define associated observables for the players, $X^A(a)$ and $Z^A(b)$ for the first player and $X^B(a)$ and $Z^B(b)$ for the second, as

$$X^A(a) = \frac{1}{2^n} \sum_{b \in \{0, 1\}^n} \sum_{\beta \in \{\pm 1\}} (N^{1\beta}_{ab} - N^{-1\beta}_{ab}), \quad Z^A(b) = \frac{1}{2^n} \sum_{a \in \{0, 1\}^n} \sum_{\alpha \in \{\pm 1\}} (M^{1\alpha}_{ab} - M^{-1\alpha}_{a,b}). \quad (11)$$
Likewise, there exist observables \( X^B(a) \) and \( Z^B(b) \) for the second player are defined similarly.

Finally we use \( X^A(a, b) \) and \( Z^A(a, b) \) to denote the observables defined via (6) from Alice’s strategy upon questions \((q_X, a, b)\) and \((q_Z, a, b)\) respectively.

### 4.2 Statement of results

We state the analysis of the Pauli braiding test in two parts: first we show that success in the test implies that observables (11) constructed from Alice and Bob’s measurement operators approximately obey certain relations; then we show that these relations imply the existence of a local isometry under which the operators are close to operators satisfying the relations exactly.

**Theorem 13.** Suppose a strategy \((N, |\psi\rangle_{AB})\) succeeds in the Pauli braiding test (Figure 2) with probability at least \( \omega_{\text{pauli}} - \epsilon \), when the game \( G_{ac} \) is an \((\omega_{ac}^*, \delta)\) anticommutation game. Then the following approximate relations hold, where operators \( W^D \) are defined in (11) for \( W \in \{X, Z\} \) and \( D \in \{A, B\} \) and \( \rho = |\psi\rangle\langle\psi| \).

1. (Approximate consistency) For \( W \in \{X, Z\} \), \( E_a d_\rho(W^A(a), W^B(a)) = O(\epsilon) \);
2. (Approximate linearity) For \( W \in \{X, Z\} \), \( E_{a,b} d_\rho(W^A(a)W^B(b), W^A(a + b)) = O(\sqrt{\epsilon}) \);
3. (Approximate anticommutation) \( E_{a,b} d_\rho(X^A(a)Z^A(b), -Z^A(b)X^A(a)) = O(\delta(\epsilon)) \);
4. (Approximate commutation) \( E_{a,b} d_\rho(X^A(a)Z^A(b), Z^A(b)X^A(a)) = O(\epsilon^{1/4} + \delta(\epsilon)^{1/2}) \).

We note that the constant \( \omega_{\text{pauli}}^* \) is given by

\[
\omega_{\text{pauli}}^* = \frac{2}{3} + \frac{1}{3} \omega_{ac}^* \tag{12}
\]

where \( \omega_{ac}^* \in (0, 1] \) is the winning parameter associated with the \((\omega_{ac}^*, \delta)\) anticommutation game \( G_{ac} \) used in the protocol. Thus if \( \omega_{ac}^* = 1 \) then \( \omega_{\text{pauli}}^* = 1 \) as well.

**Theorem 14.** Suppose given a bipartite state \(|\psi\rangle_{AB} \in \mathcal{H}_A \otimes \mathcal{H}_B \), and observables \( \{X^A(a)\}_{a \in \{0, 1\}^n}, \{Z^A(b)\}_{b \in \{0, 1\}^n} \) on \( \mathcal{H}_A \) and \( \{X^B(a)\}_{a \in \{0, 1\}^n}, \{Z^B(b)\}_{b \in \{0, 1\}^n} \) on \( \mathcal{H}_B \) such that conditions 1, 2, and 3. in Theorem 13 are satisfied, for some \( \epsilon > 0 \) and \( \delta(\epsilon) = O(\frac{1}{\sqrt{\epsilon}}) \). Then there exists a state

\[
|\Psi\rangle_{AB} = |\psi\rangle_{AB} \otimes |\text{EPR}\rangle_{A'A''} \otimes |\text{EPR}\rangle_{B'B''} \in (\mathcal{H}_A \otimes (\mathbb{C}_2^A \otimes \mathbb{C}_2^{A''})^\otimes \mathcal{H}_B \otimes (\mathbb{C}_2^B \otimes \mathbb{C}_2^{B''})^\otimes \mathcal{A}\mathcal{A}'\mathcal{A}''\mathcal{B}\mathcal{B}'\mathcal{B}'')
\]

and observables \( \{P^A(a, b)\} \) on \( AA'\mathcal{A}''\mathcal{B}\mathcal{B}'\mathcal{B}'' \) such that, if \( \rho = |\Psi\rangle\langle\Psi| \),

(a) (Approximate consistency) \( E_a d_\rho(P^A(a, 0), X^A(a) \otimes I_{A'A''})^2 = O(\epsilon^{1/8}) \) and \( E_b d_\rho(P^A(0, b), Z^A(b) \otimes I_{A'A''})^2 = O(\epsilon^{1/8}) \).

(b) (Pauli braiding) For all \( a, b, a', b' \in \{0, 1\}^n \), \( P^A(a, b)P^A(a', b') = (-1)^{a'b} P^A(a + a', b + b') \).

Likewise, there exist observables \( \{P^B(a, b)\} \) on \( BB'\mathcal{B}'\mathcal{B}'' \) satisfying analogous relations.

---

\(^4\)The restriction on \( \delta \) is not necessary, but it is satisfied for both the CHSH and Magic Square games, and simplifies the presentation.
We note that the Pauli braiding relations expressed in (b) imply the existence of an isomorphism such that the operators $P^A(a, b)$ (resp. $P^B(a, b)$) are mapped to “true” Pauli operators $\sigma^A_X(a)\sigma^A_Z(b)$ (resp. $\sigma^B_X(a)\sigma^B_Z(b)$).

The proofs of Theorem 13 and Theorem 14 are given in Sections 4.3 and Section 4.4 respectively. Before moving to the proofs we state an immediate, but powerful, application of the theorems to the problem of establishing dimension witnesses. For this it is sufficient to note the following well-known fact:

**Fact 15.** Let $\rho$ be a density matrix on $\mathbb{C}^n \otimes \mathbb{C}^n$ and $\epsilon > 0$ such that

$$\frac{1}{2^n} \sum_{P \in \{X, Z\}^n} \text{Tr}((\sigma_P \otimes \sigma_P)\rho) \geq 1 - \epsilon,$$

where $\sigma_P = \sigma_{P_1} \otimes \cdots \otimes \sigma_{P_n}$. Then

$$\langle \text{EPR}^{\otimes n} | \rho \otimes \text{EPR} \rangle \geq 1 - \epsilon.$$

**Proof.** Observe that $\text{Tr}(\langle \text{EPR}|\text{EPR}\rangle) \geq \frac{1}{2}(\sigma_X \otimes \sigma_X + \sigma_Z \otimes \sigma_Z)$.

Combining this fact and Theorems 13 and 14 gives the following consequence: a robust self-test for $n$ EPR pairs.

**Corollary 16.** Suppose given a strategy $(N, |\psi\rangle_{AB})$ for the players in the Pauli braiding test (Figure 2) with success probability $\omega^*_{\text{pauli}} - \epsilon$, for some $\epsilon > 0$. Then there exists a local isometry $\Phi = (\Phi^A : \mathcal{H}_A \rightarrow \mathcal{H}_A' \otimes \mathcal{H}_A'', \Phi^B : \mathcal{H}_B \rightarrow \mathcal{H}_B' \otimes \mathcal{H}_B'')$ such that

$$\text{Tr} \left( (\langle \text{EPR}\rangle_{A'B'} \otimes I_{A''B''}) (\Phi^A \otimes \Phi^B(|\psi\rangle\langle\psi|_{AB})) (\text{EPR}\rangle_{A'B'} \otimes I_{A''B''}) \right) = 1 - O(\epsilon^{1/8}).$$

By instantiating the anticommutation game $G_{\text{ac}}$ used in the test with the Magic Square game we obtain a robust self-test for $n$ EPR pairs in which the optimal strategy only requires the use of $(n + 1)$ EPR pairs and is accepted with probability $\frac{5}{4}$.

4.3 Proof of Theorem 13

The proof of Theorem 13 proceeds by analyzing each of the three subtests performed in the Pauli braiding test separately, and then putting them together to establish the three conditions claimed in the theorem. We give the proof of the theorem now, assuming the results on each subtest established in Lemma 17, Lemma 18 and Lemma 19 below.

**Proof of Theorem 13** Given a strategy $(N, |\psi\rangle_{AB})$ for the players, define observables $X^A(a), Z^A(b)$ and $X^B(a), Z^B(b)$ as in (11). Property 1. of approximate consistency is established by the consistency test (Lemma 17). Property 2. of approximate linearity follows from the Linearity Test (Theorem 11). When $a \cdot b = 1 \mod 2$, the approximate anticommutation property is established by the anticommutation test (Lemma 18). When $a \cdot b = 0 \mod 2$ the corresponding commutation is proved in Lemma 19.

---

5In fact, for the case of the Magic Square game it is not hard to see that there always exists an optimal strategy in the test using $\max(2, n)$ EPR pairs.
4.3.1 Consistency Test

The following lemma states consequences of the consistency test we will use.

**Lemma 17.** Suppose the strategy \((N, |\psi\rangle)\) succeeds in the consistency test with probability \(1 - \epsilon\). Then there exists \(\epsilon_{\text{stab}} = O(\epsilon)\) such that

\[
E_a \ d_\rho(X^A(a), X^B(a))^2 \leq \epsilon_{\text{stab}} \quad \text{and} \quad E_b \ d_\rho(Z^A(b), Z^B(b))^2 \leq \epsilon_{\text{stab}},
\]

and

\[
E_{a,b|a=b=1} \ d_\rho(X^A(a), X^B(a))^2 \leq \epsilon_{\text{stab}} \quad \text{and} \quad E_{a,b|a=b=1} \ d_\rho(Z^A(b), Z^B(b))^2 \leq \epsilon_{\text{stab}}.
\]

Moreover, the honest strategy succeeds in the consistency test with probability \(1 - \epsilon\).

**Proof.** It follows from the definition of \(C_\rho\) that any strategy \((N, |\psi\rangle)\) succeeding in the test with probability \(1 - \epsilon\) satisfies

\[
\frac{1}{2} \left( E_{a,b|a=b=1} C_\rho(X^A(a), X^B(a)) + E_a C_\rho(X^A(a), X^B(a)) \right) = 1 - O(\epsilon)
\]

\[
\frac{1}{2} \left( E_{a,b|a=b=1} C_\rho(Z^A(b), Z^B(b)) + E_b C_\rho(Z^A(b), Z^B(b)) \right) = 1 - O(\epsilon).
\]

The first part of the lemma follows directly by applying (5) to the above relations. The second part follows from the definition of the honest strategy and the fact that

\[
\sigma_X \otimes \sigma_X |\text{EPR}\rangle = \sigma_Z \otimes \sigma_Z |\text{EPR}\rangle = |\text{EPR}\rangle.
\]

\[\square\]

4.3.2 Anticommutation test

The (approximate) Pauli braiding relations state that

\[
X^A(a) Z^A(b) |\psi\rangle \approx (-1)^{a \cdot b} Z^A(a) X^A(b) |\psi\rangle.
\]

There are two cases: if \(a \cdot b = 0 \mod 2\) then the two operators should commute; otherwise, they should anti-commute. The anticommutation test enforces the latter property. In Section 4.3.3 we show how the former can be derived as a consequence.

**Lemma 18.** Suppose the game \(G_{ac}\) used in the anticommutation test is an \((\omega_{ac}^*, \delta)\) anticommutation game. Suppose the strategy \((N, |\psi\rangle)\) succeeds in the anticommutation test with probability \(\omega_{ac}^* - \epsilon_{ac}\) and in the consistency test with probability \(1 - \epsilon_{\text{stab}}\). Then

\[
E_{a,b|a=b=1} d_\rho(X^A(a) Z^A(b), (-1)^{a \cdot b} Z^A(a) X^A(b)) = O(\delta(\epsilon_{ac})) + O(\sqrt{\epsilon_{\text{stab}}}).
\]

Moreover, the honest strategy succeeds in this test with probability \(\omega_{ac}^*\).

**Proof.** By definition of the soundness condition of an \((\omega_{ac}^*, \delta)\) anticommutation game, the observables \(X^T(b, a)\) and \(Z^T(a, b)\) satisfy

\[
E_{a,b|a=b=1} d_\rho(X^T(a, b) Z^T(a, b), (-1)^{a \cdot b} Z^T(a, b) X^T(a, b)) = O(\delta(\epsilon_{ac})).
\]

Using the triangle inequality, Lemma\[17\] (note that under the uniform distribution \(a \cdot b = 1\) with probability at least 1/4 and Lemma\[6\]

\[
E_{a,b|a=b=1} d_\rho(X^B(a) Z^B(b), (-1)^{a \cdot b} Z^B(b) X^B(a)) = O(\delta(\epsilon_{ac})) + O(\sqrt{\epsilon_{\text{stab}}}),
\]

and analogue relations hold for observables on Alice, using again Lemma\[17\] \[\square\]
4.3.3 Commutation

The protocol does not involve a test for commutation, as the required property can be derived as a consequence of the existing tests.

Lemma 19. Suppose the strategy \((N, \psi)\) succeeds in the linearity and consistency tests with probability at least \(1 - \epsilon_{\text{stab}}\) and in the anticommutation test with probability at least \(\omega_{ac} - \epsilon_{ac}\). Then

\[
\mathbb{E}_{\sigma, b, a \cdot b = 0} d_{\rho}(X^A(a)Z^A(b) - Z^A(b)X^A(a))^2 = O(\delta(\epsilon_{ac})^{1/2}) + O(\epsilon_{\text{stab}}^{1/4}).
\]

Proof. We combine the anticommutation, linearity, and consistency tests through the following sequence of approximate identities. Note the approximations are taken under the uniform distribution on \(n\)-bit strings \(a, b\) such that \(a \cdot b = 0 \mod 2\). Since this event occurs with probability at least \(1/2\) for uniform \(a, b\), the conditioning does not affect any of the approximations used by more than a multiplicative factor 2.

Start by applying approximate linearity (guaranteed by Theorem 11) of \(Z\) to express \(Z(b)\) as a product \(Z(c)Z(c + b)\), for uniformly random \(c\) such that \(c \cdot a = 1 \mod 2\):

\[
X^A(a)Z^A(b)\psi \approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\epsilon^{1/4}_{\text{stab}}} X^A(a)Z^A(c)Z^A(c + b)|\psi
\]

Next use approximate consistency (Lemma 17), to exchange \(Z^B(c + b)\) for \(Z^A(c + b)\):

\[
\approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\epsilon^{1/4}_{\text{stab}}} Z^B(c + b)X^A(a)Z^A(c)\psi
\]

Next, apply approximate anticommutation (Lemma 18) to anti-commute \(X^A(a)\) and \(Z^A(c)\):

\[
\approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\delta^{1/2} + \epsilon^{1/4}_{\text{stab}}} - Z^B(c + b)Z^A(c)X^A(a)\psi
\]

Applying Lemma 17 again, transfer \(Z^B(c + b)\) back to Alice:

\[
\approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\epsilon^{1/4}_{\text{stab}}} - Z^A(c)X^A(a)Z^A(c + b)|\psi
\]

Applying Lemma 18 anti-commutes \(Z^A(c + b)\) and \(X^A(a)\):

\[
\approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\delta^{1/2} + \epsilon^{1/4}_{\text{stab}}} Z^A(c)Z^A(c + b)X^A(a)|\psi
\]

Use Lemma 17 to transfer \(X^A(a)\) to Bob:

\[
\approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\epsilon^{1/4}_{\text{stab}}} X^B(a)Z^A(c)Z^A(c + b)|\psi
\]

Finally apply Theorem 11 to combine the \(Z\) operators, and then Lemma 17 to move the \(X\) operator back to Alice:

\[
\approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\epsilon^{1/4}_{\text{stab}}} X^B(a)Z^A(b)|\psi
\]

\[
\approx \frac{a,b,c|a \cdot b = 0, c \cdot a = 1}{\epsilon^{1/4}_{\text{stab}}} Z^A(b)X^B(a)|\psi.
\]

\[\square\]
4.4 Proof of Theorem 14

We give the proof of Theorem 14.

Proof of Theorem 14: Adjoin two $n$-qubit registers $A'$ and $A''$ to Alice's system, and initialize them in the state $|\text{EPR}_{A'A''}\rangle$. Define new observables $X'(a) := X^A(a) \otimes \sigma_X(a)_{A'} \otimes I_{A''}$ and $Z'(b) := Z^A(b) \otimes \sigma_Z(b)_{A'} \otimes I_{A''}$. Further define observables

$$C(a, b) := \frac{X'(a)Z'(b) + Z'(b)X'(a)}{|X'(a)Z'(b) + Z'(b)X'(a)|},$$

where the notation $| \cdot |$ denotes the matrix absolute value and we use the convention $0/0 = 1$. We use the assumptions made in the theorem (i.e. properties 1, 2 and 3 in Theorem 13) to show that $C(a, b)$ satisfies approximate linearity over $Z_2^n$, i.e. that $C(a, b)C(a', b')|\Psi\rangle \approx^{a,b,a',b'} C(a + a', b + b')|\Psi\rangle$. First, by property 3 (approximate anticommutation), $X^A(a)Z^A(b)|\Psi\rangle \approx^{a,b} (-1)^{a-b}Z^A(a)X^A(b)|\Psi\rangle$, and thus $X'(a)Z'(b)|\Psi\rangle \approx^{a,b} Z'(b)X'(a)|\Psi\rangle$. Hence, by Lemma 7 it follows that $C(a, b)|\Psi\rangle \approx^{a, b} X'(a)Z'(b)|\Psi\rangle$. Using this relation, we consider the product of two $C$ operators.

$$C(a, b)C(a', b')|\Psi\rangle \approx^{a,b} C(a, b)X^A(a')Z^A(b') \otimes \sigma_X(a')\sigma_Z(b')|\Psi\rangle.$$

By property 1 (approximate consistency), we can switch the $X^A$ and $Z^A$ operators to Bob, and switch the $\sigma_X, \sigma_Z$ operators to the other half of the ancilla. Then, we relate $C(a, b)$ to $X^A(a)Z^A(b)$.

$$\approx^{a,b,a',b'} Z^B(b')X^B(a')C(a, b) \otimes \sigma_Z(b')_{A''}\sigma_X(a')_{A''}|\Psi\rangle \approx^{a,b,a',b'} Z^B(b')X^B(a')X^A(a)Z^A(b) \otimes \sigma_Z(b')_{A''}\sigma_X(a')_{A''}\sigma_X(a)\sigma_Z(b)|\Psi\rangle.$$

Switching $Z^B X^B$ back to Alice, and $\sigma_Z \sigma_X$ back to the other half of the ancilla,

$$\approx^{a,b,a',b'} X^A(a)Z^A(b)X^A(a')Z^A(b') \otimes \sigma_X(a)\sigma_Z(b)\sigma_X(a')\sigma_Z(b')|\Psi\rangle.$$

By the properties of the exact Pauli operators,

$$=^{a, b, a', b'} (-1)^{a-b}X^A(a)Z^A(b)X^A(a')Z^A(b') \otimes \sigma_X(a + a')\sigma_Z(b + b')|\Psi\rangle.$$

Applying property 3 (approximate anticommutation),

$$\approx^{a,b,a',b'} (-1)^{a-(b+b')}X^A(a)Z^A(b)Z^A(b')X^A(a') \otimes \sigma_X(a + a')\sigma_Z(b + b')|\Psi\rangle.$$

Applying property 1 (approximate consistency) to $X^Z(a')$, and then property 2 (approximate linearity) to combine $Z^A(b)$ with $Z^A(b')$, we get

$$\approx^{a,b,a',b'} (-1)^{a-(b+b')}X^B(a')X^A(a)Z^A(b + b') \otimes \sigma_X(a + a')\sigma_Z(b + b')|\Psi\rangle.$$

Applying property 3 (approximate anticommutation) to $Z^A(b + b')$ and $X^A(a)$,

$$\approx^{a,b,a',b'} (-1)^{(a+a')-(b+b')}X^B(a')Z^A(b + b')X^A(a) \otimes \sigma_X(a + a')\sigma_Z(b + b')|\Psi\rangle.$$
Applying Theorem 10 (over $b \in E$).

Finally, applying property 3 (approximate anticommutation) to interchange $X^{A}(a + a')$ and $Z^{A}(b + b')$,

$$
\approx_{\epsilon^{1/4}}^{a,b,a',b'} \frac{1}{(a+a')(b+b')} Z^{A}(b+b') X^{A}(a+a') \otimes \sigma_{X}(a+a') \sigma_{Z}(b+b') |\Psi\rangle.
$$

Finally, applying property 3 (approximate anticommutation) to interchange $X^{A}(a + a')$ and $Z^{A}(b + b')$,

$$
\approx_{\epsilon^{1/8}}^{a,b,a',b'} X^{A}(a+a') Z^{A}(b+b') \otimes \sigma_{X}(a+a') \sigma_{Z}(b+b') |\Psi\rangle
$$

$$
\approx_{\epsilon^{1/8}}^{a,b,a',b'} C(a+a', b+b') |\Psi\rangle.
$$

Applying Theorem 10 (over $\{0,1\}^{2n}$), we conclude that there exist observables $D(a,b)$ acting on an extension of Alice’s system by an ancilla state, satisfying $D(a,b)D(a',b') = D(a+a', b+b')$ and $E_{a,b} d_{\rho}(D(a,b), C(a,b))^{2} = O(\epsilon^{1/8})$. Set

$$
P^{A}(a,b) := D(a,b) \otimes \sigma_{X}(a)_{A''} \sigma_{Z}(b)_{A''}.
$$

We claim that $P^{A}(a,b)$ satisfies the desired properties.

(b) Pauli braiding: This follows from linearity of $D(a,b)$:

$$
P^{A}(a,b)P^{A}(a',b') = D(a,b)D(a',b') \otimes \sigma_{X}(a)_{A''} \sigma_{Z}(b)_{A''} \sigma_{X}(a')_{A''} \sigma_{Z}(b')_{A''}
$$

$$
= D(a+a', b+b') \otimes (-1)^{a''-b''} \sigma_{X}(a+a')_{A''} \sigma_{Z}(b+b')_{A''}
$$

$$
= (-1)^{a''-b''} P^{A}(a+a', b+b').
$$

(a) Approximate consistency: We establish this in two steps. First, note that $D(a,b)$ is approximately consistent with $C(a,b)$, so

$$
P^{A}_{a,b} |\Psi\rangle = a,b D(a,b) \otimes \sigma_{X}(a)_{A''} \sigma_{Z}(b)_{A''} |\Psi\rangle
$$

$$
\approx_{\epsilon^{1/8}}^{a,b} C(a,b) \otimes \sigma_{X}(a)_{A''} \sigma_{Z}(b)_{A''} |\Psi\rangle
$$

$$
\approx_{\epsilon^{1/8}}^{a,b} X^{A}(a) Z^{A}(b) \otimes \sigma_{X}(a)_{A''} \sigma_{Z}(b)_{A''} |\Psi\rangle
$$

$$
= a,b X^{A}(a) Z^{A}(b) \otimes I_{A''} |\Psi\rangle,
$$

where the last line follows since both $\sigma_{X} \otimes \sigma_{X}$ and $\sigma_{Z} \otimes \sigma_{Z}$ stabilize $|\text{EPR}\rangle$.

Finally, to establish consistency for the operators $P^{A}(a,0)$ where one coordinate is fixed to 0, we exploit the exact Pauli braiding relation:

$$
P^{A}(a,0) |\Psi\rangle = a,c,d (-1)^{d-c} P^{A}(a+c,d) P^{A}(c,d) |\Psi\rangle
$$

By approximate consistency of $P^{A}$,

$$
\approx_{\epsilon^{1/8}}^{a,c,d} (-1)^{d-c} P^{A}(a+c,d) X^{A}(c) Z^{A}(d) |\Psi\rangle
$$

24
Applying property 1 (approximate consistency) twice, first to $Z^A(d)$ and then to $X^A(c)$, we shift them to Bob’s space:

$$\approx^{a,c,d} \sqrt{\epsilon} (-1)^{a,c} Z^B(d)X^B(c)P^A(a+c,d)|\Psi\rangle$$

Now we apply approximate consistency of $P^A$ again:

$$\approx^{a,c,d} \epsilon \sqrt{\epsilon} Z^B(d)X^B(c)X^A(a+c)Z^A(d)|\Psi\rangle$$

Applying property 3 (approximate anticommutation) to $X^A(a+c)$ and $Z^A(d)$, and then property 1 (approximate consistency) to $X^B(c)$, we get

$$\approx^{a,c,d} \epsilon Z^B(d)Z^A(d)X^A(a+c)X^A(c)|\Psi\rangle$$

We use property 2 (approximate linearity) to combine $X^A(a+c)$ and $X^A(c)$:

$$\approx^{a,c,d} \epsilon Z^B(d)Z^A(d)X^A(a)|\Psi\rangle$$

Now, applying property 3 (approximate anticommutation), we get,

$$\approx^{a,c,d} \epsilon Z^B(d)X^A(a)Z^A(d)|\Psi\rangle$$

Finally, use property 1 (approximate consistency), and the fact that $Z^A(d)$ is an observable to get

$$\approx^{a,c,d} X^A(a)Z^A(d)Z^A(d)|\Psi\rangle$$

$$=^{a,c,d} X^A(a)|\Psi\rangle.$$
a bipartite entangled state across any one of its qubits and the others, is maximally entangled. This allows us to lift the two-player tests which constitute the Pauli braiding test to \( r \)-player tests, where each player holds one qubit (“share”) of the encoding of each qubit of the ground state, and one of the players (to be called the special player) plays the role of Alice while the remaining \((r - 1)\) players (to be called the composite player) play the role of Bob.

The essential property of the constituent tests of the Pauli braiding test that permit this lifting is that all of the measurements performed by Bob in the honest strategy can be implemented by measuring the tensor product of Pauli operators \( \sigma_X, \sigma_Z, \) and \( I \) on a state of \( n \) EPR pairs. (For the anticommutation test, this is ensured by the completeness condition in Definition 8 and for the other tests, it can be seen to hold for both Alice and Bob’s measurements). These operators can be implemented transversally in any CSS code, and moreover in a way such that marginal distribution of queries received by the special player and each of the composite players is identical, as we show below.

### 5.1 The protocol

We describe the protocol in detail. The input is an \( n \)-qubit local Hamiltonian \( H \) that can be expressed as

\[
H = \frac{1}{m} \sum_{\ell=1}^{m} H_\ell, \quad H_\ell = \alpha_\ell \sigma_X(a_\ell)\sigma_Z(b_\ell),
\]

for \( \alpha_\ell \in [-1, 1] \) and \( a_\ell, b_\ell \in \{0, 1\}^n \) such that \( a_\ell \land b_\ell = 0^n \) for all \( \ell \in \{1, \ldots, m\} \). The verifier interacts with \( r \) players, where \( r \) is the number of qubits of codewords in the CSS code chosen for the protocol (such as Steane’s 7-qubit code, as described in Section 2.2 in which case \( r = 7 \)).
Given a local Hamiltonian $H = \sum_{\ell=1}^{m} \alpha_{\ell} H_{\ell}$, where $\alpha_{\ell} \in [-1, 1]$ and each $H_{\ell} = \sigma_X(a_{\ell}) \sigma_Z(b_{\ell})$. Let $p \in (0, 1)$ be a parameter of the protocol.

The verifier performs one of the following three tests at random, the first with probability $(1 - p)$ and the second and third with probability $p/2$ each.

1. (Pauli braiding test) Choose one of the $r$ players uniformly at random to be the special player. The other players form the composite player. Simulate the Pauli braiding test with these two players, where the role of Alice is assigned to the special player and the role of Bob to the composite player.

2. (Energy test) Choose $\ell \in \{1, \ldots, m\}$ uniformly at random. Define an operator $Q_{\ell}$ acting on $rn$ qubits by replacing each $\sigma_X$ in $H_{\ell}$ with $X_{\text{logical}}$ on the $r$-qubit code state, and $\sigma_Z$ by $Z_{\text{logical}}$. Send each player a query $(XZ, a, b)$ representing the associated share of $Q_{\ell}$. The players should each return two values in $\{-1, 1\}$. The verifier takes the product of all values received. If its sign disagrees with that of $\alpha_{\ell}$, he accepts. If they agree, he rejects with probability $|\alpha_{\ell}|$ and accepts otherwise.

3. (Energy consistency test) Choose one of the $r$ players uniformly at random to be the special player. The other players form the composite player. Let $W \in \{X, Z\}$, each chosen with probability $1/2$. Also choose $a, b$ according to the same distribution as in the energy test. The verifier performs one of the following tests, each chosen with the indicated probability.

   - With probability $1/2$, send the special player $(XZ, a, b)$, and the composite player $(W, c, c + a)$ if $W = X$ and $(W, c, c + b)$ if $W = Z$, where $c \in \{0, 1\}^n$ is chosen uniformly at random. Accept if the special player’s answer agrees with the product of the composite player’s two answers.

   - With probability $1/4$, send the special player $(W, c, d)$, and the composite player $(W, c, c + a)$, where $c, d \in \{0, 1\}^n$ are chosen uniformly at random. Accept if the special player and composite player agree on the answer associated with $c$.

   - With probability $1/4$, send the special player $(W, c + a, d)$, and the composite player $(W, c, c + a)$, where $c, d \in \{0, 1\}^n$ are chosen uniformly at random. Accept if the special player and composite player agree on the answer associated with $c + a$.

Figure 3: The Hamiltonian self-test

Although the protocol is to be performed with $r$ “physical” players, part of the protocol consists in applying the Pauli braiding test, which is formulated as a two-player test in the previous section. To translate between the $r$ players and the two players in the Pauli braiding test we introduce two “logical” players. A query to the logical players (as specified in the Pauli braiding test) is mapped to a query to the $r$ physical players as follows. One of the physical players is chosen at random to play the role of the first logical player (Alice), called the special player. The remaining $(r - 1)$ physical players together play the role of the second logical player (Bob), called
the composite player. For a given query $Q$ to the special player of a type among those specified in the Pauli braiding test we define a complementary query $\overline{Q}$ for the composite player as per the following lemma.

**Lemma 20.** For any $X$-query or $Z$-query, there exists a complementary query $\overline{Q}$ such that

1. The query associated to each physical player forming the composite player in $\overline{Q}$ is of the same type as $Q$. In particular the distribution on query strings is as specified by the query type.

2. If all players apply the honest strategy and provide answers $\alpha, \beta$ to $Q$ and $\bar{\alpha}, \bar{\beta}$ to $\overline{Q}$ respectively, where $\bar{\alpha}$ and $\bar{\beta}$ are each obtained as the product of the answer to the corresponding query coming from each of the physical players making up the composite player, it holds that $\alpha \bar{\alpha} = \beta \bar{\beta} = +1$.

**Proof.** Both items follow from the properties of CSS codes described in Section 2.2. We give the proof for an $X$-query $(X,a,b)$. Let the index of the special player be $i \in \{1, \ldots, r\}$, and let $S_X$ be a stabilizer of the code, such that $S_X$ consists only of $I$ and $\sigma_X$ Paulis and has a $\sigma_X$ in position $i$. For each physical player $j \neq i$ associated with the composite player, if the operator in position $j$ of $S_X$ is $\sigma_X$, player $j$ is sent the query $(X,a,b)$. Otherwise, player $j$ is sent a uniformly random $X$-query $(X,c,d)$.

Composite answers $\alpha, \beta$ to the complementary query are determined by taking the product of the answers from all players who did not receive random strings; using that $S_X$ is a stabilizer of the code ensures that item 2 is satisfied.

In the composite query, for a given choice of $S_X$ each player receives a query that is either identical to the original query, or is a uniformly random string; since the original query is chosen at random this is also the case for each of the physical players associated with the composite player. This proves item 1.

We can then define associated observables for the players, $\hat{X}(a)$ and $\hat{Z}(b)$ for the special player and $\overline{X}(a)$ and $\overline{Z}(b)$ for the composite player, exactly as in (11).

**Definition 21.** Let $\{\hat{M}_{a,b}^{\alpha\beta}\}$ (resp. $\{\overline{M}_{a,b}^{\alpha\beta}\}$) be the POVM implemented by the special player (resp. composite player) when asked a query $(W,a,b)$ (resp. $(\overline{W},a,b)$; see Lemma 20), for $W = X$ or $Z$. Define observables

$$W(a) = \frac{1}{2^n} \sum_{b \in \{0,1\}^n} \sum_{\beta \in \{\pm 1\}} (\hat{M}_{a,b}^\beta - \hat{M}_{a,b}^{-\beta}) \quad \overline{W}(a) = \frac{1}{2^n} \sum_{b \in \{0,1\}^n} \sum_{\beta \in \{\pm 1\}} (\overline{M}_{a,b}^\beta - \overline{M}_{a,b}^{-\beta})$$

Aside from the Pauli braiding test, the protocol considers two other tests called the energy test and the energy consistency test. In the energy test, the verifier asks the players to measure a randomly chosen term in the Hamiltonian. The consistency test is needed to relate the operators applied in the energy test to those applied in the Pauli braiding test. The energy test uses an additional query type, which differs from the types of queries used in the Pauli braiding test:

---

6The physical players remain isolated throughout the protocol and are never allowed to communicate; it is only for purposes of analysis that we group $(r - 1)$ physical players into a single logical player. In particular the physical players are never told which logical player they are associated with, and the distribution of queries to any physical player is the same whether it plays the role of the special or composite player.
3. An XZ-query is represented by \((XZ, a, b)\) where \(a, b \in \{0, 1\}^n\) are such that \(a \wedge b = 0^n\). Note that here, in contrast to \(X\) or \(Z\)-queries, the strings \(a\) and \(b\) are ordered. The distribution on \(a\) and \(b\) depends on the Hamiltonian. The expected answer is two bits \(\alpha, \beta \in \{-1, 1\}\).

The honest strategy for the players in the Hamiltonian self-test (Figure 3) consists of applying the honest strategy defined for the Pauli braiding test (Definition 12) whenever the query is of \(X\), \(Z\), or \(G\) type, and the following strategy when it is of \(XZ\) type:

**Definition 22.** In the honest strategy, a player answers an XZ-query \((XZ, a, b)\) by measuring the compatible observables \(\sigma_X(a)\) and \(\sigma_Z(b)\) and returning both outcomes.

### 5.2 Statement of results

Our main result regarding the Hamiltonian self-test is given in the following theorem, which states the completeness and soundness guarantees of the protocol described in Figure 3.

**Theorem 23.** There exists a constant \(0 < d < 1\) such that the following holds. Let \(H\) be a (not necessarily local) Hamiltonian with \(m\) terms over \(n\) qubits of the form \((1),\) and \(\lambda_{\text{min}}(H)\) the smallest eigenvalue of \(H\). Then for every \(\eta > 0\) there is a choice \(p = \Theta(\eta^{1-d})\) for the probability of performing the energy test in Protocol 3 such that the maximum probability \(\omega^*(H)\) with which any \(r\)-player strategy succeeds in the protocol satisfies

\[
1 - \frac{p}{8}\left(\lambda_{\text{min}}(H) + \frac{2}{m} \sum_{\ell=1}^{m} |\alpha_\ell|\right) \leq \omega^*(H) \leq 1 - \frac{p}{8}\left(\lambda_{\text{min}}(H) + \frac{2}{m} \sum_{\ell=1}^{m} |\alpha_\ell|\right) + \eta.
\]

Corollary 2 follows from Theorem 23 by an amplification step described in Section 5.5. The proof of the theorem relies on the analysis of the energy test and the energy consistency test, given in Section 5.3 and Section 5.4 respectively, together with the analysis of the Pauli braiding test given in Section 4.2.

**Proof of Theorem 23** First we establish the lower bound. An honest quantum strategy (as described in Definition 12 and Definition 22) acting on an encoded ground state \(|\Gamma\rangle\) of \(H\), together with an encoding of the additional EPR pairs \(|\text{EPR}^{(m-1)}\rangle\) required to implement an optimal strategy in the anticommutation game \(G_{\text{ac}}\) (recall we take \(G_{\text{ac}} = \text{MS}\) in this section, so \(\omega_{\text{ac}} = 1, \delta(\epsilon) = O(\sqrt{\epsilon})\), and \(m = 2\)) succeeds in the protocol with probability \(\omega^\text{honest}(H) = (1 - p) + p \omega^\text{energy}(H)\), where

\[
\omega^\text{energy}(H) = \frac{1}{2} + \frac{1}{4} \left(1 - \frac{1}{4}\lambda_{\text{min}}(H) - \frac{1}{2m} \sum_{\ell=1}^{m} |\alpha_\ell|\right)
\]

denotes the probability of the honest strategy to pass in the energy and consistency tests, each executed with probability \(1/2\); the analysis of the energy test is from Lemma 24.

Next we establish the upper bound. Suppose a strategy for the players succeeds with overall probability \(\omega_{\text{cheat}}\), passes the Pauli braiding test with probability \(1 - \epsilon\), and passes the energy and consistency tests with probability \(\omega_{\text{energy}}\); thus \(\omega_{\text{cheat}} = (1 - p)(1 - \epsilon) + p \omega_{\text{energy}}\). Applying the combination of Theorem 13 and Theorem 14 there exists an \((rn)\)-qubit state \(|\varphi_1\rangle\) on which the action of the Pauli operators \(\sigma_X, \sigma_Z\) is \(O(\epsilon^{1/8})\)-consistent with the action of the players’ operators \(X, Z\) in the cheating strategy. Further, Lemma 25 shows that the measurements performed in the
energy test are $O(\epsilon^d)$-consistent, for some $0 < d < 1$, with the corresponding product of players' $X$ and $Z$ operators from the Pauli test. Combining these two statements we deduce that an honest strategy using the shared state $|\varphi_1\rangle$ will succeed in the Pauli braiding test with probability 1 (since it is honest and $\omega_{ac} = 1$), and in the energy test with probability at least $\omega_{\text{energy}} - O(\epsilon^d)$. Since this strategy implements valid logical $X$ and $Z$ operators in the energy test, by lemma 24 it passes the test with probability at most $\omega_{\text{honest}}$. Thus

$$\omega_{\text{honest}} \leq \omega_{\text{energy}}(H) - O(\epsilon^d).$$

Choosing $p$ to be a sufficiently small constant times $\eta^{1-d}$, for all $0 \leq \epsilon \leq 1$ this expression is less than or equal to $\omega_{\text{honest}}(H) + \eta$.

5.3 Analysis of the energy test

The goal of the energy test is to estimate the energy of a randomly chosen term in the Hamiltonian.

**Lemma 24.** Given a Hamiltonian $H$ as in (13), the acceptance probability of the energy test, when the correct Pauli operators are applied by each player on its respective register of the $(rn)$-qubit encoding of an $n$-qubit state $|\psi\rangle$, is

$$\omega_{\text{energy}}(H, |\psi\rangle) = 1 - \left( \frac{1}{2m} \sum_{\ell=1}^{m} |\alpha_\ell| + \alpha_\ell |\langle \psi | H_\ell |\psi\rangle|^2 \right)$$

$$= 1 - \left( \frac{1}{4} |\langle \psi | H |\psi\rangle| + \frac{1}{2m} \sum_{\ell=1}^{m} |\alpha_\ell| \right),$$

where $H_\ell = \sigma_X(a_\ell)\sigma_Z(b_\ell)$ is the $\ell$-th term in the Hamiltonian.

**Proof.** The proof is a simple calculation in all points similar to that performed in [Ji16a, Section 4]; see in particular the discussion that precedes Theorem 23 in that paper. We omit the details.

5.4 Analysis of the consistency test

The goal of the energy consistency test is to guarantee that operators used by the special player on $XZ$-type queries are consistent with those used on other types of queries.

**Lemma 25.** Suppose the strategy $(N, |\psi\rangle)$ for the players succeeds in the energy consistency test and the Pauli braiding test with probability $1 - \epsilon$ each. Then

$$\frac{1}{m} \sum_{\ell=1}^{m} \| (\hat{H}_\ell - \hat{X}(a)\hat{Z}(b)) |\psi\rangle \|^2 = O(\epsilon^{1/32}),$$

where $a$ and $b$ are strings such that $H_\ell = \sigma_X(a)\sigma_Z(b)$, and $\hat{H}_\ell$ is the observable applied by the special player upon receiving the query $(XZ, a, b)$ in the energy test.

Moreover, the honest strategy succeeds in the test with probability 1.
Proof. We show that $XZ$-queries, $X$-queries, and $Z$-queries on the special player are all consistent with $(X, c, c + a)$ and $(Z, c, c + b)$ queries to the composite player. The analysis uses similar techniques to the analysis of the linearity test. First, let us analyze the case when the verifier chooses $W = X$. Let the POVM applied by the composite player be $\{\mathcal{M}_{c,c+a}^\alpha\}$ and define marginalized operators

$$\mathcal{M}_{c,c+a}^\alpha = \sum_{\alpha'} \mathcal{M}_{c,c+a}^{\alpha\alpha'}.$$  

Likewise, let the POVM applied by the special player be $\hat{P}_{a\alpha'}$ and define marginalized operators for the special player:

$$\hat{H}_{a\alpha}^\alpha = \sum_{\alpha'} \hat{P}_{a\alpha'}^{\alpha\alpha'}, \quad \hat{H}_{b\alpha}^{\alpha'} = \sum_{\alpha} \hat{P}_{b\alpha}^{\alpha\alpha'},$$

The observable $\hat{H}_\ell$ corresponding to the product of the special player’s measurement outcomes is defined as

$$\hat{H}_\ell = \sum_{\alpha\alpha'} (-1)^{\alpha\cdot\alpha'} \hat{P}_{a\alpha'}^{\alpha\alpha'}.$$  

Recall that the Pauli braiding test (Theorem 14) guarantees the existence of operators $P^{A}(a, b)$ exactly satisfying the Pauli relations; let

$$X(a) := P^{A}(s, 0) \quad \text{and} \quad Z(b) := P^{A}(0, b).$$  

Item (a) of Theorem 14 guarantees that $X(a)$ (resp. $Z(b)$) is within $O(\epsilon^{1/8})$ of $\hat{X}(a)$ (resp. $\hat{Z}(b)$), in the state-dependent distance $d_P$. Associated with the observable $X(a)$ are the projectors $X^{\alpha\alpha}(a)$, $\alpha \in \{\pm 1\}$, and likewise $Z^{\beta\beta}(b)$ for $Z(b)$.

The following relations follow from the assumption that the players succeed with probability $1 - \epsilon$ in the energy consistency test. We use the notation $E_{\ell, a \sim H_\ell}$ to indicate that the index $\ell$ is chosen uniformly at random, and then the string $a$ is chosen from the distribution of queries induced by the Hamiltonian term $H_\ell$; in contrast to $E_a$ which indicates a uniformly random string.

$$E_{\ell, a \sim H_\ell} E_c C_\rho (\mathcal{M}_{c,c+a}^\alpha, \hat{X}^\alpha(c)) = 1 - O(\epsilon), \quad (14)$$

$$E_{\ell, a \sim H_\ell} E_c C_\rho (\mathcal{M}_{c,c+a}^{\alpha\alpha}(c + a), \hat{X}^{\alpha\alpha}(c + a)) = 1 - O(\epsilon), \quad (15)$$

$$E_{\ell, a \sim H_\ell} E_c C_\rho \left( \hat{H}_{a\alpha}^\alpha, \sum_{\beta, \beta' = \alpha} \mathcal{M}_{c,c+a}^{\beta\beta'} \right) = 1 - O(\epsilon). \quad (16)$$

We use these relations to show that the special player’s marginalized measurement $\hat{H}_{a\alpha}^\alpha$ is close to $X^{\alpha\alpha}(a)$. We show this in two steps. First, we relate the special player’s measurement $\hat{H}_{a\alpha}^\alpha$ to the composite player’s measurement:

$$E_{\ell, a \sim H_\ell} C_\rho \left( \hat{H}_{a\alpha}^\alpha, X^{\alpha\alpha}(a) \right) \geq E_{\ell, a \sim H_\ell} E_c C_\rho \left( \sum_{\beta, \beta' = \alpha} \mathcal{M}_{c,c+a}^{\beta\beta'}, X^{\alpha\alpha}(a) \right) - d_\rho \left( \hat{H}_{a\alpha}^\alpha, \sum_{\beta, \beta' = \alpha} \mathcal{M}_{c,c+a}^{\beta\beta'} \right)$$

$$\geq E_{\ell, a \sim H_\ell} E_c C_\rho \left( \sum_{\beta, \beta' = \alpha} \mathcal{M}_{c,c+a}^{\beta\beta'}, X^{\alpha\alpha}(a) \right) - O(\sqrt{\epsilon}),$$

31
where the first inequality follows from Lemma 6 and the second from (5) and (16). Next we relate $M$ to a product of two measurements $\tilde{X}$:

$$\mathbf{E}_{\ell,a\sim\mathcal{H}_c} C_\rho \left( \hat{H}_a^{(\ell)}(\alpha) \right) \geq \mathbf{E}_{\ell,a\sim\mathcal{H}_c} \mathbf{E}_c C_\rho \left( \sum_{\beta,\beta'=\alpha} \bar{M}_c^{(\beta)}(\beta'\beta) \hat{M}_c^{(\beta)}(c) \hat{\mathcal{X}}^{(\beta)}(c+a) \mathcal{X}^{(\alpha)}(a) \right) - O(\sqrt{\varepsilon})$$

$$\geq \mathbf{E}_{\ell,a\sim\mathcal{H}_c} \mathbf{E}_c C_\rho \left( \sum_{\beta,\beta'=\alpha} \hat{\mathcal{X}}^{(\beta)}(c) \hat{\mathcal{X}}^{(\beta')}(c+a) \mathcal{X}^{(\alpha)}(a) \right) - O(\sqrt{\varepsilon}),$$

as follows from (15), (14) and Lemmas 6 and (5). Finally, we use the Pauli braiding test to relate $\tilde{X}$ to the exactly linear observable $\mathcal{X}$. Starting from the above and using Lemma 17 to switch $\tilde{X}(c)$ to $\tilde{X}(c)$,

$$\mathbf{E}_{\ell,a\sim\mathcal{H}_c} C_\rho \left( \hat{H}_a^{(\ell)}(\alpha) \right) \geq \mathbf{E}_{\ell,a\sim\mathcal{H}_c} \mathbf{E}_c C_\rho \left( \sum_{\beta,\beta'=\alpha} \hat{\mathcal{X}}^{(\beta)}(c) \hat{\mathcal{X}}^{(\beta')}(c+a) \mathcal{X}^{(\alpha)}(a) \right) - O(\sqrt{\varepsilon}).$$

Next, we use Theorem 14 and Lemma 6 to sequentially exchange the remaining $\tilde{X}$, then $\tilde{X}$, to $\mathcal{X}$, to obtain

$$\mathbf{E}_{\ell,a\sim\mathcal{H}_c} C_\rho \left( \hat{H}_a^{(\ell)}(\alpha) \right) \geq \mathbf{E}_{\ell,a\sim\mathcal{H}_c} \mathbf{E}_c C_\rho \left( \sum_{\beta,\beta'=\alpha} \mathcal{X}^{(\beta)}(c) \mathcal{X}^{(\beta')}(c+a) \mathcal{X}^{(\alpha)}(a) \right) - O(\varepsilon^{1/16}). \quad (17)$$

Finally, the product of the three $\mathcal{X}$ operators can be eliminated using the exact linearity relations. Performing an analogous analysis for the $Z$ operators,

$$\mathbf{E}_{\ell,b\sim\mathcal{H}_c} C_\rho \left( \hat{H}_b^{(\ell)}(\beta) \right) \geq 1 - O(\varepsilon^{1/16}). \quad (18)$$

To put these results together it remains to apply the stabilizer property to these operators. While we cannot do this directly since $a$ and $b$ are not distributed uniformly, we can use the exact linearity to write $Z(b) = \mathbf{E}_c Z(b+c)Z(c)$, and apply Lemma 17 to each term in the product:

$$\hat{H}_\ell |\psi\rangle = \hat{H}_a^{(\ell)} \hat{H}_b^{(\ell)} |\psi\rangle$$

$$= \hat{H}_a^{(\ell)} \hat{H}_b^{(\ell)} |\psi\rangle$$

by (18), Lemma 6 and (5)

$$= \mathbf{E}_c Z(b+c)Z(c) |\psi\rangle$$

by exact linearity

$$= \mathbf{E}_c Z(c) Z(b+c) \mathcal{X}(a) |\psi\rangle$$

by Theorem 14 and Lemma 17

$$= \mathbf{E}_c \mathcal{X}(a) Z(b+c)Z(c) |\psi\rangle$$

by Theorem 14 and Lemma 17

$$= \mathcal{X}(a) Z(b) |\psi\rangle$$

by exact linearity.

$\square$

5.5 Amplification

In this section we show how Theorem 23 can be used to obtain Corollary 2. The main idea consists in leveraging the fact that our protocol does not require locality of the Hamiltonian to first “brute-force” amplify the gap of the underlying instance of the local Hamiltonian problem to a constant,
and then run the protocol on the amplified non-local instance. This is achieved by first shifting the Hamiltonian by the appropriate multiple of identity so that the energy in the yes-instance is less than or equal to 0. The gap is amplified by taking sufficiently many tensor product copies of the Hamiltonian, resulting in a non-local instance.

**Lemma 26 (Gap amplification).** Let $H$ be an $n$-qubit Hamiltonian with minimum energy $\lambda_{\text{min}}(H) \geq 0$ and such that $\|H\| \leq 1$. Let $p(n), q(n)$ be polynomials such that $p(n) > q(n)$ for all $n$. Let

$$H' = I^\otimes a - (I -(H - a^{-1} I))^\otimes a,$$

where $a = \left(\frac{1}{q} - \frac{1}{p}\right)^{-1}$.

Then $H'$ is a (non-local) Hamiltonian over $an = O(np(n))$ qubits with $\|H'\| = O(1)$, such that if $\lambda_{\text{min}}(H) \leq 1/p$, then $\lambda_{\text{min}}(H') \leq 1/2$, whereas if $\lambda_{\text{min}}(H) \geq 1/q$, then $\lambda_{\text{min}}(H') \geq 1$.

**Proof.** The proof follows by observing that $\lambda_{\text{min}}(H') = 1 - (1 - (\lambda_{\text{min}}(H) - a^{-1}))^a$, and $(1 \pm \delta)^k = 1 \pm k\delta + O(\delta^2)$ when $k\delta = O(1)$. \qed

**Proof of Corollary 2.** By applying the result of Theorem 23 to the Hamiltonian $H'$ obtained from $H$ as in Lemma 26 we obtain the statement of Corollary 2 except with $p_c = p$ and $p_b = q$ for some constants $0 < q < p < 1$. To match the constants in the statement of Corollary 2, we make the verifier automatically accept with probability $1 - p'$, and perform the test with probability $p'$, for some $0 \leq p' \leq 1$. Then we get $p_c = 1 - p' + p'p$ and $p_b = 1 - p' + p'q$. If $p'$ is chosen as $p' = \frac{1}{2(1 + p - 2q)}$, we get $p_c = 1/2 + 2\eta_0$ and $p_b = 1/2 + \eta_0$ as desired, with $\eta_0 = \frac{(p-q)}{2(1+p-2q)}$. \qed

### 6 Delegated Computation

It was noticed in [FH15] that an interactive proof system for the local Hamiltonian problem can also be used for delegated quantum computation with so-called *post-hoc* verification. The key idea is to use the Feynman-Kitaev construction to produce a Hamiltonian encoding the desired computation; measuring the ground energy of this Hamiltonian reveals whether the computation accepts or rejects. Following the same connection, we are able to give a post-hoc verifiable delegated computation scheme with a purely classical verifier and a constant number of players. The players only need the power of BQP. The scheme has a constant completeness-soundness gap independent of the size of the circuit to be computed, unlike the scheme of [FH15] and the classical scheme of [RUV13], which both have inverse-polynomial gaps. However, unlike the scheme of [RUV13] (and similarly to the one in [FH15]), our protocol is not blind: the verifier must reveal the entire circuit to be computed to all the players before the verification process starts.

**Theorem 27.** There exists an interactive proof system for BQP with seven quantum entangled players and one classical verifier, with one round of communication, in which the player sends $O(\text{poly}(n))$-bit questions and receives $O(1)$-bit answers. The honest players only need the power of BQP.

**Proof sketch.** For any poly-size quantum circuit $C$, we construct the history Hamiltonian $H_C$ and announce to the seven players. In the honest case, the players produce the state

$$|\psi\rangle = \text{ENC}\left(\frac{1}{\sqrt{T}} \sum_{t=1}^{T} |t\rangle_{\text{clock}} \otimes |\psi_t\rangle\right),$$

33
where ENC is the encoding map of the 7-qubit code, $t$ labels the clock states of the computation from 1 to $T$, and $|\psi_t\rangle$ is the state of the circuit $C$ at step $t$. This state can be prepared with a BQP machine. The players are then separated; in the honest case, each player receives a share of the encoded state $|\psi\rangle$. The verifier plays the game of Theorem 23 with the players and accepts if and only if they succeed.
