Future space borne gravitational wave detectors will require a precise definition of calibration signals to ensure the achievement of their design sensitivity. The careful design of the test signals plays a key role in the correct understanding and characterisation of these instruments. In that sense, methods achieving optimal experiment designs must be considered as complementary to the parameter estimation methods being used to determine the parameters describing the system. The relevance of experiment design is particularly significant for the LISA Pathfinder mission, which will spend most of its operation time performing experiments to characterise key technologies for future space borne gravitational wave observatories. Here we propose a framework to derive the optimal signals —in terms of minimum parameter uncertainty— to be injected to these instruments during its calibration phase. We compare our results with an alternative numerical algorithm which achieves an optimal input signal by iteratively improving an initial guess. We show agreement of both approaches when applied to the LISA Pathfinder case.

I. INTRODUCTION

LISA Pathfinder [?] is an ESA mission with NASA contributions designed to test key technologies for the detection of gravitational waves in space, like the propose eLISA [?]. The main scientific goal for the mission is expressed in terms of a differential acceleration noise between two test masses in nominally geodesic motion down to a level of $S_{\Delta a} = 3 \times 10^{-14} \, \mathrm{m/s^2}/\sqrt{\mathrm{Hz}}$ at $3 \, \mathrm{mHz}$. The relevance of this requirement is not only its demand in terms of noise reduction but also the very low frequency measuring band, which introduces technological difficulties that can not be addressed by ground based gravitational wave detectors due to the so called seismic wall [?].

The LISA Pathfinder mission is currently planned to have a six month operations period at the Lagrange point L1 that will be split between the two experiments on-board: the European LISA Technology Package (LTP) and the American Disturbance Reduction System (DRS). This leads to a very short operation period of roughly three months for the complete characterisation and achievement of the scientific goal for the LTP.

It is worth noticing that, after the demonstration of the technology readiness, a second —yet not less relevant– objective of the mission is a detailed characterisation of the noise contributions to the main scientific measurement. An extensive list of experiments has been put forward by the scientific team including experiments to characterise the optical metrology [?], the inertial sensor instrument [?], the effects of the thermal [?] and magnetic [?] environment, and pure free-fall experiments that aim to measure acceleration noise in an configuration that is even more representative of eLISA [?]. All these runs need to be executed via tele-commands using a daily 8 hours communication window with the satellite. Internal constraints in pre-processing and validation of tele-commands will add a latency from 2 to 3 days between the definition of a tele-command sequence and its execution on the spacecraft.

The planning of experiments represents therefore a crucial part of the mission and needs to be optimised accordingly to make sure that the information obtained from each experiment is maximised. As part of this effort a MATLAB toolbox has been developed with the specific aim to deal with the LTP data during flight operations [?]. Among the different methods and capabilities of this tool, much attention has been paid to the improvement of the methods to obtain precise parameters from the experiments [? ? ? ?]. These have been tested with simulated data, taking into account the expected noise performance of the Pathfinder mission, in a series of mock

data challenges with data generating using the analysis software's built-in modeling and simulation tools. Agreement between methods was also checked with data generated from an independent spacecraft simulator developed by the prime industrial contractor, as was the case in the LISA Pathfinder operational exercises [?].

These analyses focused on the parameter estimation strategy and the achievement of an optimal precision in the parameters obtained, following the heritage of previous simulated data exercises, like for instance the LISA Mock Data Challenge [?] that focused on the problem of astrophysical parameter estimation from LISA data. Unlike the problem of astrophysical data analysis, in the LISA Pathfinder case, the measured signal is the response of the LISA Pathfinder system to some injected input signal that was specified by the telecommand file. In other words, there exists the opportunity in LISA Pathfinder to design the injected signals so that the measurement of the system parameters is optimised. The operators of ground-based gravitational-wave detectors have a similar opportunity to design signals when characterising the response of their instruments to various noise sources but, given their easy access to their instruments, not as much emphasis is placed on optimising signal injections. LISA Pathfinder thus represents a scenario where careful signal design would produce the most benefit.

In the following we propose a general framework which allows the optimisation of the input signals applied to a given system. Experiment design can be described in most cases as an optimisation problem for a given figure of merit, which typically relates to an scalar of the Fisher information matrix [? ?]. Although the description used here applies to a general case, in the current work we will be mostly interested in the application to the estimation of the main parameters governing the combined dynamics of the test mass and the spacecraft in LISA Pathfinder. Hardware on-board the satellite imposes us a further limitation which is only to consider sinusoidal signals as input signals.

This work is organised as follows. In section II we introduce the problem of experiment design and the notation used in this work. Section III describes a numerical algorithm to optimise the signal to be injected given a model, and its application to a simple case. In section IV we introduce the LISA Pathfinder model used for our analysis in section V and finally present our conclusions.

II. FISHER MATRIX ANALYSIS

A. Definitions and notation

In the following we will describe a given system as

$$\vec{o}(\omega) = \mathbf{H}(\omega; \Theta) \, \vec{s}(\omega) + \vec{n}(\omega) \tag{1}$$

where $\vec{o}$ is a vector with the measurements being considered, $\vec{s}$ is a vector with injection signals that can be

applied to test the system and $\mathbf{H}(\omega; \Theta)$ is the matrix whose components, $H_{ij}(\omega; \Theta)$, contain the transfer function describing the dynamics of the system in the frequency domain with a dependence on a set of parameters $\Theta = \{\theta_1, \cdots, \theta_N\}$. $\vec{n}(\omega)$ describes the noise contribution of our instrument.

The likelihood function is the probability to observe a measurement for a given set of parameters describing that system. Assuming that the data is Gaussian distributed, the likelihood for our system will be

$$p(\vec{o}|\Theta) = [2\pi\mathbf{\Sigma}]^{-1/2} \exp[-\frac{1}{2}(\vec{o} - \mathbf{H}(\Theta) \cdot \vec{s})\mathbf{\Sigma}^{-1}(\vec{o} - \mathbf{H}(\Theta) \cdot \vec{s})] \tag{2}$$

where $\mathbf{\Sigma}$ is the noise covariance matrix. Experiment design is based on the analysis of the Fisher matrix, whose elements are defined as

$$F_{ij} = \left\langle \left(\frac{\partial \log(p(\vec{o}|\Theta))}{\partial \Theta_i} \right)^T \left(\frac{\partial \log(p(\vec{o}|\theta))}{\partial \theta_j} \right) \right\rangle \Bigg|_{\theta_0} \tag{3}$$

which can be used to set limit for expected covariance matrix of the parameters, know as the Crámer-Rao bound [?]

$$\text{cov}[\theta_i, \theta_j] \geq \mathbf{F}^{-1} \tag{4}$$

The decomposition of the Fisher matrix into eigenvalues and eigenvectors will prove to be very useful in the following sections. Given a N×N Fisher matrix $\mathbf{F}$, defined by a set of N parameters, the eigenvectors $\vec{u}$ and eigenvalues, λ, always fulfil

$$\mathbf{F} \, \vec{u} = \lambda \, \vec{u} \tag{5}$$

The eigenvectors can be used to diagonalize the Fisher matrix according to the following property

$$\mathbf{F} = \mathbf{R^T} \, \mathbf{\Lambda} \, \mathbf{R} \tag{6}$$

where the columns of the matrix $\mathbf{R}$ are the (normalised) eigenvectors of $\mathbf{F}$ and $\mathbf{\Lambda}$ is a diagonal matrix with the eigenvalues in the diagonal. Notice that $\mathbf{R}$ can be understood as a rotation matrix that can be used to express the vector of our initial parameters, $\vec{\Theta}$, in the new diagonal basis $\vec{u}$,

$$\vec{\zeta} = \mathbf{R} \, \vec{\Theta} \tag{7}$$

from where we obtain our new set of parameters in the diagonal basis, $\vec{\zeta}$.

B. Fisher matrix tomography

To compute the Fisher matrix we need to follow Eq.(3). We notice though that even for this simplified problem the straightforward application of this expression leads to long expression that make difficult a further analytical treatment. To avoid cumbersome expression as much

as possible we expand the Fisher matrix in its different composing terms. In the particular case of an experiment with M inputs and N outputs, we may write the elements of our Fisher matrix as:

$$F_{ij} = \sum_{n,q=1}^{M} \sum_{m,p=1}^{N} F_{mnpq,ij} \tag{8}$$

where

$$F_{mnpq,ij} = \{\boldsymbol{\Sigma}^{-1}\}_{mp} \left[\partial_{\theta_i} H_{mn}(\Theta)\right]^T \left[\partial_{\theta_j} H_{pq}(\Theta)\right] s_n s_q \tag{9}$$

The definition of the Fisher matrix allows us to combine the information of different experiments by adding their Fisher matrices. However, in this case, we use this same property in the opposite direction: to split a single experiment as the combination of simpler independent experiments. This tomography —from the greek *tomos*, which means "part"— will be particularly useful to interpret the Fisher matrix since we can split each experiment into the contribution of each transfer function and study them independently. The $F_{mnpq,ij}$ term can be understood as the $mp-$component of a Fisher matrix corresponding to an experiment which only considers a sinusoidal input applied to the $nq-$channels. We notice here that if the noise covariance matrix, $\{\boldsymbol{\Sigma}^{-1}\}_{mp}$, would be diagonal we could consider each $F_{mnpn,ij}$ as the contribution corresponding to a given transfer function $H_{mn}(\Theta)$. However, cross-couplings between our channels imply a mixing of the different transfer function contributions.

III. NUMERICAL DESIGN OF INPUT SIGNALS

The analytical solution has a limited application and becomes unfeasible for complex systems. A more flexible and general approach is to iteratively optimise the input spectrum based on a scalar criterion. As we discussed above, a useful choice for this purpose is to use the determinant of the covariance matrix which is a measure of the volume of the uncertainty ellipsoid. For computational simplicity, the inverse of the Fisher matrix is used as an approximation of the covariance matrix. Since we are working in a high SNR regime, it is also a good approximation.

The experimental design problem can be stated as how to choose an input signal that allows the optimisation of the function $\det[\mathbf{F}^{-1}]$ given the constraints of our particular experiment. The literature suggests several options for a scalar figure of merit to use as a minimisation criteria including the minimisation of the trace of the inverse of the Fisher matrix and the maximisation of the determinant of the Fisher matrix. In our case, we will stick to the latter as it is the equivalent to minimising the uncertainty ellipsoid in the parameter space.

This can be done analytically for simple models although no closed form exist for most problems. The usual strategy is to describe the problem as a numerical minimisation problem as we show below.

A. Dispersion function

The dispersion function $\nu(\omega)$ is a useful tool for experiment design. As shown below, it can be used iteratively to improve the input spectrum. For a given an input spectrum

$$\chi(\omega) = (|X(\omega_1)|^2 \ldots |X(\omega_F)|^2) \quad \text{with} \sum_{k=1}^{F} |X(\omega_k)|^2 = 1 \tag{10}$$

the dispersion function is defined as [?]

$$\nu(\omega) = \text{trace}\left[\mathbf{F}^{-1}(\chi)\mathbf{F}(\omega)\right] \tag{11}$$

where $\mathbf{F}(\chi)$ is the information matrix from the power spectrum $\chi(\omega)$ and $\mathbf{F}(\omega)$ is the information matrix from a single frequency input with normalised power spectrum $|X(\omega)|^2 = 1$. The dispersion function defined in this way has some interesting properties. In particular, it can be shown that the dispersion function is proportional to the variance of the transfer function of the system and that it is normalised to the number of unknown parameters, N_θ.

Given the previous properties of the dispersion function, we can build an algorithm that minimises the covariance matrix in an iterative way. The steps to do so are the following:

1. Select a set of frequencies $\{\omega_1, \ldots \omega_F\}$ within the frequency band of interest and distribute the power equally over these frequencies. This constitutes the initial design.

2. Compute the dispersion function for the F frequencies.

3. Create a new design according to:

$$\chi_{i+1}(\omega_k) = \chi_i(\omega_k) \times \nu_i(\omega_k)/N_\theta \tag{12}$$

4. If $\max(\nu(\chi_i, \omega_k)) - N_\theta < \epsilon$ for a sufficient small ϵ, then the optimum design is found. If not, we return to step 2.

It can be shown that the algorithm converges to an optimal design. [?]

In order to prove the efficiency of the previous numerical design method we test it in the case of a harmonic oscillator. We can analytically compute the Fisher matrix for this problem to obtain an expression which, as expected, shows a maximum of the spectrum at the natural frequency of the oscillator, ω_0. This value is therefore the one that minimises the volume of the error ellipsoid in the parameter space and hence, the one that the numerical method described in the previous section should retrieve.

In order to check the validity of our methodology, we generated a time series of $10\,000$ seconds of white noise with variance $\sigma = 10^{-5}$ that we consider as our initial input design. We choose white noise in order to weight all
FIG. 1. Evolution of the algorithm to optimise the input signal for the harmonic oscillator case. The algorithm promotes the natural frequency of the oscillator $\omega_0 = 0.07$.

frequencies equally. We consider an harmonic oscillator with damping ratio $\xi = 0.01$ and natural frequency $\omega_0 = 0.07$, and then we run the algorithm as described above. The result is shown in Fig. 1 where we show the evolution of the input signal as proposed by the algorithm. As shown, two iterations are enough for the algorithm to promote the natural frequency of the oscillator ω_0 among the others.

IV. LISA PATHFINDER MODEL

In order to apply this methodology to LISA Pathfinder we will need first to define a model for the experiment. In the following we introduce the notation to describe the combined dynamics of the two test masses and the satellite required for the analysis. The same description with small variations can also be found in [? ? ?].

A. Equation of motion

The measurement on-board the satellite is usually expressed as

$$\vec{o} = (\mathbf{D} \cdot \mathbf{S}^{-1} + \mathbf{C})^{-1}(-\mathbf{C}\,\vec{o}_i + \vec{g}_n + \mathbf{D} \cdot \mathbf{S}^{-1}\vec{o}_n) \ (13)$$

where $\mathbf{D}$ is the dynamical matrix, $\mathbf{C}$ is the controller, and $\mathbf{S}$ stands for the sensing matrix, which translates the physical position of the test masses into the interferometer readout, $\vec{o}$. Subindex n stands for noise quantities, either sensing noise ($\vec{o}_n$) or force noise ($\vec{g}_n$), and subindex i stands for the injected signals ($\vec{o}_i$). Restricting ourselves to linear motion along the axis between the two test masses (the degree of freedom that is measured by the interferometer), each of the dynamical variables

in (14) can be expressed as 2-dimensional vectors with components referring to the x_1 and x_Δ channels respectively,

$$\vec{o} = \begin{pmatrix} o_1 \\ o_\Delta \end{pmatrix}, \quad \vec{o}_i = \begin{pmatrix} o_{i1} \\ o_{i\Delta} \end{pmatrix},$$

$$\vec{o}_n = \begin{pmatrix} o_{n1} \\ o_{n\Delta} \end{pmatrix}, \quad \vec{g}_n = \begin{pmatrix} g_{n1} - g_N \\ g_{n2} - g_{n1} \end{pmatrix},$$

where subindicies 1 and 2 refer to the first and second test mass, subindex Δ refers to differences between the first and second test mass, and capitalised subindices (such as force noise on the spacecraft, g_N) refer to the spacecraft. The last equation in (14) shows how g_N is only measured in the first channel. On the other hand, the differential channel is sensitive to any differential force noises applied to the first and the second test masses.

The matrices describing the dynamics of the LISA Pathfinder system are:

$$\mathbf{D} = \begin{pmatrix} s^2 + \omega_1^2 + \frac{m_1}{m_{\mathrm{SC}}}\omega_1^2 + \frac{m_2}{m_{\mathrm{SC}}}\omega_2^2 & \frac{m_2}{m_{\mathrm{SC}}}\omega_2^2 \\ \omega_2^2 - \omega_1^2 & s^2 + \omega_2^2 \end{pmatrix},$$

$$\mathbf{C} = \begin{pmatrix} H_{\mathrm{df}} & 0 \\ 0 & H_{\mathrm{sus}} \end{pmatrix}, \qquad (14)$$

$$\mathbf{S} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix},$$

where ω_1 and ω_2 are the stiffnesses — the steady force gradient across the test mass housing per unit mass [?] — coupling the motion of each test mass to the motion of the spacecraft; H_{df} and H_{sus} are the drag-free and suspension loops controllers, respectively. For the remainder of this work, it is assumed that H_{df} and H_{sus} are known.

For our current analysis we will assume some approximations in these expressions in order to keep the main scientific information and, at the same time, keep the expressions as simple as possible. For that reason, in the following we will eliminate the back reactions terms, $m_1 = m_2 << m_{\mathrm{SC}}$, consider that the sensing matrix cross-couplings are zero $S_{12} = S_{21} = 0$. For convenience, we will take the calibrations $S_{11} = S_{22} = 1$. Taking into account these assumptions we can derive expressions for the transfer functions describing the system. We consider input signals injected at the guidance input port which we expressed as o_i in Eq.(14), hence the transfer function is defined by

$$\mathbf{H} = (\mathbf{D} \cdot \mathbf{S}^{-1} + \mathbf{C})^{-1}(-\mathbf{C}) \cdot \vec{o}_i$$
$$= \begin{pmatrix} H_{11}(\Theta) & H_{12}(\Theta) \\ H_{21}(\Theta) & H_{22}(\Theta) \end{pmatrix} \begin{pmatrix} o_{i1} \\ o_{i\Delta} \end{pmatrix} \qquad (15)$$

TABLE I. LPF noise model parameters . p_2 and p_4 parameters correspond to frequencies in [Hz] and p_1 to amplitude spectral densities in [m/$\sqrt{\text{Hz}}$] and [N/$\sqrt{\text{Hz}}$] for read-out noise and force noise, respectively.

	NOISE PARAMETERS		
Parameter	$o_{n1}/o_{n\Delta}$	g_{n1}/g_{n2}	g_N
p_1	3.6×10^{-12}	7×10^{-15}	2.5×10^{-10}
p_2	10×10^{-3}	5×10^{-3}	12×10^{-3}
p_3	4.2	3	3.8
p_4	1.8×10^{-3}	4×10^{-4}	1×10^{-3}
p_5	8	8	8

where the transfer functions are given by

$$H_{11} = \frac{H_{\text{df}}}{\omega^2 - \omega_1^2 + H_{\text{df}}} \tag{16}$$

$$H_{12} = 0 \tag{17}$$

$$H_{21} = \frac{H_{\text{df}} (\omega_2^2 - \omega_1^2)}{(\omega^2 - \omega_1^2 + H_{\text{df}})(\omega^2 - \omega_2^2 + H_{\text{lfs}})} \tag{18}$$

$$H_{22} = \frac{H_{\text{lfs}}}{\omega^2 - \omega_2^2 + H_{\text{lfs}}} \tag{19}$$

where we realise that H_{12} is zero because this is proportional to the parameter S_{12}, which we consider to be zero. At the same time, we see that the cross-coupling from drag-free to differential channel, H_{21}, is proportional to the differential stiffness, $\omega_2^2 - \omega_1^2$.

B. Noise model

Our study of the injection scheme in LISA Pathfinder relies on the Fisher matrix which, in turn, depends on the noise model used for those noise sources identified in Eq.(14). These are: interferometer read-out noise for both channels —o_{n1} and $o_{n\Delta}$— force noise applied to the test masses —g_{n1} and g_{n2}— and force noise applied to the spacecraft —g_N. Following [?], we will characterise each of these with the five parameters, $p_{1\ldots 5}$ in the expression

$$S(\omega) = p_1 \left(1 + \frac{1}{\left(\frac{\omega}{2\pi p_2}\right)^{p_3}} + \frac{1}{\left(\frac{\omega}{2\pi p_4}\right)^{p_5}} \right)^{1/2}. \tag{20}$$

Applying the parameters in Table I we obtain the models in Fig. 2 for the noise spectra of the two main interferometer channels. We can compare the predictions from this simplified model to simulations coming from a detailed state-space simulator containing a much elaborate model of the instrument, for instance delays, actuators, and component noise models [?]. As seen in Fig. 2, our simple parametric model agrees well with the noise obtained from the state-space model.

FIG. 2. Comparison of the noise spectra for the two main interferometers channels for an analytical simple model (dashed line) and a noise data stream generated via a LPF state-space model (solid line).

V. CALIBRATION SIGNALS FOR LISA PATHFINDER DYNAMICS

During operations, LISA Pathfinder will run an exhaustive characterisation campaign with the objective of calibrating the instrument and identifying the main noise contributions. Here we consider one set of experiments targeting the calibration of the dynamical parameters governing the combined motion of the two test masses and the satellite. For these particular set of experiments, the calibration procedure consists of the injection of a sequence of sinusoids — the only available waveform in the flight software — at different frequencies at a number of input ports. For this work, we will focus on injection in one of the two main interferometer channels. However, the methodology can be easily applied to the remaining degrees of freedom.

A. The F_{2121} term

In order to demonstrate our method we consider an injection applied to the drag-free channel. In our framework this experiment would be completely described by the sum

$$F_{ij} = \sum_{m,p} F_{m1p1,ij} \tag{21}$$

where the indices i and j run over the parameters. The most general case (7 degrees of freedom) correspond to 49 terms. This is not approachable analytically so we focus our attention on one term with particular relevance, the F_{2121}, which can be expressed as:

$$F_{2121,ij} = \{\mathbf{\Sigma}^{-1}\}_{22} \times$$
$$[\partial_{\theta_i} H_{21}(\omega)]^T [\partial_{\theta_j} H_{21}(\omega)] |o_1(\omega)|^2 \tag{22}$$
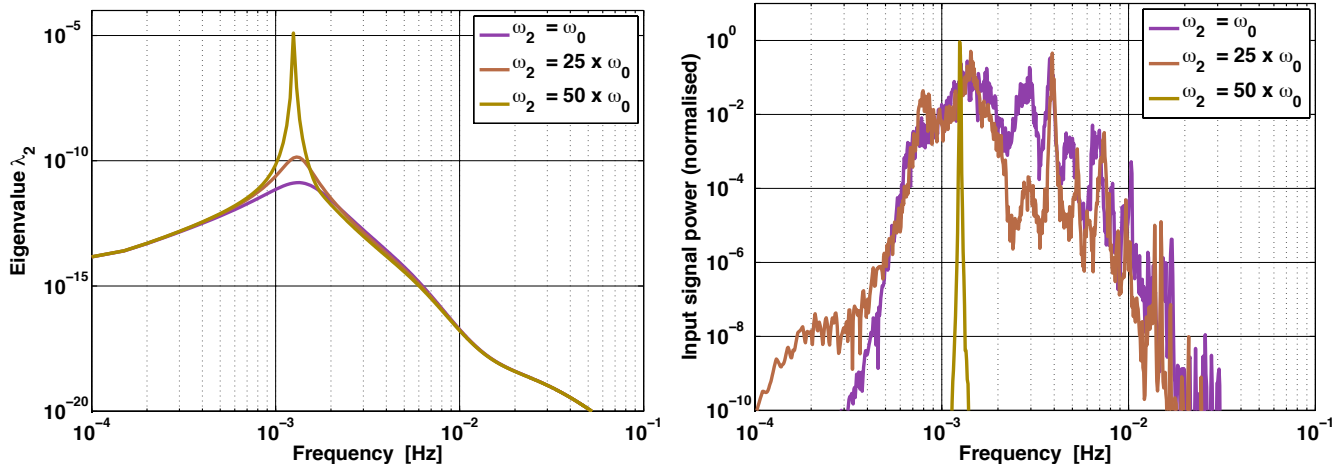

FIG. 3. *Left*: evaluation of the eigenvalue λ_2 of the F_{2121} term for a single frequency injection. *Right*: Output of the numerical algorithm for the optimisation of input signals based on the dispersion function applied to a LISA Pathfinder state-space model after 25 iterations. In this case, white noise was injected into the drag-free channel. In both cases (analytical and numerical) the analysis is repeated by rescaling a factor 25 and 50 the value of the second test mass stiffness, which is originally considered to be $\omega_0^2 = -22 \times 10^{-6}\,\text{s}^{-2}$.

This term quantifies the effect of the injection in the first channel as measured by the highly-sensitive differential channel. Under the assumptions discussed in sec. IV A, the only parameters that impact this term are the two test mass stiffnesses, which enter through the term in Eq. (18). Due to this simplification, we can describe this problem in analytical terms. Eq.(22) turns into a 2×2 matrix that we can easily decompose in the related eigenvectors,

$$\vec{u_1} = \begin{bmatrix} \dfrac{\alpha(\omega_1)\,\beta(\omega_1)}{\alpha(\omega_2)\,\beta(\omega_2)} \\ 1 \end{bmatrix} \quad \vec{u_2} = \begin{bmatrix} -\dfrac{\alpha(\omega_2)\,\beta(\omega_2)}{\alpha(\omega_1)\,\beta(\omega_1)} \\ 1 \end{bmatrix} \quad (23)$$

where

$$\alpha(x) = H_{\text{df}}(\omega) - x^2 + \omega^2 \qquad (24)$$
$$\beta(x) = H_{\text{lfs}}(\omega) - x^2 + \omega^2 \qquad (25)$$

and associated eigenvalues,

$$\lambda_1 = 0$$
$$\lambda_2 = \{\mathbf{\Sigma}^{-1}\}_{22}\, H_{\text{df}}^2(\omega)\, \frac{\alpha^2(\omega_1)\,\beta^2(\omega_1)\,\alpha^2(\omega_2)\,\beta^2(\omega_2)}{\alpha^4(\omega_1)\beta^4(\omega_2)} \quad (26)$$

Since eigenvalues are directly related to the inverse of the expected uncertainty on the associated parameter, we conclude that this measurement can only constrain parameters in the $\vec{u}_2$ direction while the direction $\vec{u}_1$ has an associated uncertainty that tends to infinity.

It is important to notice at this point that the analysis we perform in the frequency domain implicitly assumes a unique frequency, i.e. an input signal which is a sinusoid at a given frequency. In the following section we explore which information can we obtain in such a case.

1. Single tone input: undetermined solution

If we assume that the content of our input signal is a sinusoid with a fixed frequency, we know from the previous eigendecomposition that we will not be able to solve the problem since we have only one valid eigenvector for a 2-dimensional problem. Nonetheless, we explore the single frequency solution in order to determine how much information can we get from the system in such a case.

We proceed to diagonalise the Fisher matrix as in Eq. (6)

$$\mathbf{F} = \mathbf{R^T}\,\mathbf{\Lambda}\,\mathbf{R}$$

from which we obtain a diagonal system with a unique eigenvalue, λ_2, given by equation Eq.(26). In Fig. 4 we explore this expression as a function of the frequency of the injection. We see that the eigenvalue has a peak when the input is injected at a frequency around $f = 1.25\,\text{mHz}$. This becomes more evident if we increase the value of ω_2^2, as shown in the figure.

The value of $f = 1.25\,\text{mHz}$ is therefore the best frequency for a signal composed with a unique frequency component for the experiment under study. Indeed, by maximising the Fisher matrix we are reducing the error on the parameter space. However, it must be noted that this is not necessarily an optimal solution since we are dealing with a single frequency injection scheme that leads to singular Fisher matrix.

A second consideration to take into account is that when diagonalising our system, our parameters are expressed in a new basis which corresponds to applying a rotation matrix $\mathbf{R}$ to the original vector of parameters $\vec{\Theta} = \{\omega_1^2, \omega_2^2\}$. In doing so, we obtain a new set of parameters $\vec{\zeta} = \mathbf{R} \cdot \vec{\Theta}$. For the configuration under study the
FIG. 4. Determinant of the F_{2121} term for an injected signal with two independent frequencies. The determinant is evaluated for the case $\omega_2^2 = -22 \times 10^{-7}\,\mathrm{s}^{-2}$ (left) and $\omega_2^2 = 50 \times (-22 \times 10^{-7})\,\mathrm{s}^{-2}$ (right).

combination of parameters corresponding to the non-zero eigenvalue is proportional to the sum of stiffness, i.e.

$$\zeta_2 \propto \omega_1^2 + \omega_2^2 \qquad (27)$$

confirming that a single frequency signal is not able to break the degeneracy between the two parameters in our system.

We are now prepared to compare the results obtained analytically with the prediction of the numerical algorithm based on the dispersion function — Eq. (11). To do so we inject a white noise data stream to the input channel under consideration, which for the analysis of the F_{2121} term is the drag-free channel. In this particular case, we consider as our initial input a white noise time series of $10^5\,\mathrm{s}$ and $\sigma = 10^{-6}\,\mathrm{m}^2$.

In the right panel of Fig. 3 we show the resulting normalised power spectrum of the input signal as retrieved after 25 iterations of the numerical optimisation algorithm. The algorithm promotes the same frequencies that maximised the eigenvalue of the Fisher matrix F_{2121} as can be seen in the left hand figure. Moreover, we performed the analysis by rescaling the ω_2^2 value as in the study of the eigenvalues. Here we observe again how the numerical algorithm selects the f $= 1.25\,\mathrm{mHz}$ frequency when approaching the case where ω_2^2 is rescaled by a factor of 50, proving the consistency between the analytical and the numerical approach.

It is worth stressing the agreement between the two approaches shown, given that they are not based in the same description of the instrument. Whilst the analytical derivation is funded in the expressions derived here from Eq. (14), the numerical approach has its roots in the numerical computation of the dispersion function Eq. (11) which uses a state space representation of LISA

Pathfinder. The difference also lies oi how the instrument noise enter in the analysis. While we analytically compute the term Σ_{22} in Eq.(26), the noise enters in the numerical analysis through the evaluation of the Fisher matrix in Eq. (11). In the later, the noise spectrum of the instrument is computed by generating time series with the LPF state-space model configured with no signal injections and then computing the power spectrum.

2. Two tones input: full-rank solution

Here we take advantage of the analytical solution to go one step further and explore the case of an input signal composed by two sinusoids. In order to combine the information of more than one sinusoid frequency in the input signal we add the Fisher matrices corresponding to each frequency. Our experiment will therefore be described by

$$F_{2121,ij} = \sum_{k}^{N=2} \bar{F}_{2121,ij}(\omega_k) \qquad (28)$$

where each $\bar{F}_{2121,ij}(\omega_k)$ corresponds to the contribution of a single sinusoid injection to the final experiment's Fisher matrix.

We first explore the rank of the F_{2121} matrix when evaluated for different combinations of these two input frequencies. Given that F_{2121} depends on two parameters, results show that most combinations of frequencies are able to reach the condition rank$(F_{2121}) \neq 2$. In fact, only when the two frequencies are equal –and we come back to our previous case– we will not be in a full-rank situation. This allows us to go one step further and explore which combination of frequencies are optimal, in the sense of
FIG. 5. Expected error on parameters for an injection in the drag-free channel considering ω_1^2 and ω_2^2 as the only relevant parameters. Black corresponds to the initial proposal of a white noise input, blue represents the expected error for the input signal as obtained with the proposed numerical algorithm after 25 iterations.

maximising the Fisher matrix, i.e. minimising the ellipsoid error volume in the parameters space. Figure 4 shows the value for the determinant of the F_{2121} term as a function of the two injection frequencies. We explore the determinant for two different configurations of the experiment: the standard with $\omega_2^2 = -22 \times 10^{-7}\,\mathrm{s}^{-2}$ and, as before, rescaling $\omega_2^2 = 50 \times (-22 \times 10^{-7})\,\mathrm{s}^{-2}$. As expected, the determinant shows symmetry since the two injection frequencies in Eq.(28) can be interchanged producing the same output. The determinant drops to zero at the diagonal since, as commented above, an injection with two equal frequencies sinusoid does not lead to a full rank solution. It is interesting to see that when we set $50 \times \omega_2^2$, a notch appears at the frequency $\mathrm{f} = 1.25\,\mathrm{mHz}$ that we found as a maximum in the single injection case.

In the standard configuration, the maximum of the F_{2121} determinant appears for frequencies in the very low frequency regime ($\mathrm{f} < 1\,\mathrm{mHz}$). If, for practical reasons, we set one of the two injections to be $\mathrm{f}_1 = 0.1\,\mathrm{mHz}$ the maximum of the function displayed in Figure 4 appears for a second injection at $\mathrm{f}_2 = 0.3\,\mathrm{mHz}$. With these two values we can proceed to estimate the expected errors on the parameters, by evaluating the Fisher matrix in Eq.(28). By assuming two sinusoid injections with two

cycles each at the obtained frequencies $\mathrm{f}_1 = 0.1\,\mathrm{mHz}$ and $\mathrm{f}_1 = 0.3\,\mathrm{mHz}$ with and amplitude of $10^{-7}\,\mathrm{m}$, we can evaluate our expression for the Fisher matrix term F_{2121}, obtaining a $7 \times 10^{-3}\,\%$ and $6 \times 10^{-3}\,\%$ relative error estimate for the two stiffness parameters ω_1^2 and ω_2^2, respectively. It is worth reminding here that these are optimal errors representing the contribution of the F_{2121} term of the Fisher matrix to the overall experiment. We consider it as a useful example to show the capability of the framework here proposed to disentangle the different contributions to the experiment. However, the precise determination of the expected error for a given parameter requires the evaluation of the full Fisher matrix, which is composed in the analytical description of 49 components for the drag-free injection experiment. Hence, analysis considering the whole system are, in most cases, more suited for a numerical approach.

In order to evaluate the improvement on the estimate of the parameters, we run the analysis using the numerical algorithm introduced in Sec. III assuming an injection in the drag-free channel and considering only the two stiffness ω_1^2 and ω_2^2 as relevant parameters. As described above, the algorithm evaluates the Fisher matrix at each step so we can trace how the expected errors for each

parameter improve by modifying the input signal. The improvement in the error, as given by the Fisher matrix, is shown in Fig. 5, where we compare expected error on the parameters at the 1st and at the 25th iteration. The input signals associated with these two cases corresponds to a white noise injection for the first iteration that turns into a signal focusing all the power at f = 1.25 mHz after 25 iterations. The results show a clear improvement in the expected error on the parameters which decreases roughly by an order of magnitude.

VI. CONCLUSIONS

LISA Pathfinder and future space-borne gravitational wave detectors will require precise calibration of their dynamical systems in order to operate at their design sensitivities. Given the operational constraints for such missions, the design of injection signals used for calibration is a key aspect for efficient characterisation of the instrument.

We have introduced a methodology to design experiments for these instruments based on the minimisation of the uncertainty ellipsoid in parameter space. This methodology allows one to decompose the Fisher information matrix in its different contributions, each related to a unique physical coupling —or transfer function— of the experiment. By studying these contributions we can evaluate the expected error for a given spectrum of the injected test signal.

We have compared this with a numerical algorithm capable of generating an optimal input signal by iteratively improving a proposed input spectrum. The algorithm uses the dispersion function of the system to promote those frequencies which minimise the error on the parameters under study. We have applied both techniques to one example of LISA Pathfinder injection experiments, obtaining agreement in the injection signals obtained with both approaches.

As an example, we have considered the contributions to the expected error for a given term of the Fisher matrix decomposition: the F_{2121}, which describes the coupling of the x_1 (the drag-free channel) and the x_{12} (the differential channel) for the case when a signal is injected in the former. The analysis is however general and can be readily extended to other experiments within LISA Pathfinder.

The methodology proposed here is general and can be equally applied to other instruments requiring an accurate calibration in terms of parameters uncertainties, such as ground-based gravitational wave detectors.
