RUNNING TITLE:

EFFECT OF LOW HZ FIELDS ON EEG AND BEHAVIOR

Summary

A series of experiments has been done to assess the effects of low-level, low-frequency electronic fields on the behavior and EEG of monkeys. Three monkeys were implanted with subcortical and cortical EEG electrodes and trained to press a panel on a fixed interval-limited hold schedule. The monkeys were rewarded for pressing the panel once every five seconds within a 2.5-second enable period. After the animals were performing well, they were tested under low-level electric fields (2.8 volts p-p); the voltage was applied to two large metal plates 40 cm. apart so that the monkey's head was completely within the field. Fields frequency was set at 7 or 10 Hz, within the range of typical EEG recording (0-33 Hz). Four-hour daily tests of fields-on were randomly interspersed with four-hour runs with fields-off. Under the 7-Hz fields, the monkeys showed a significantly faster interresponse time in 5 of 6 experiments. Mean differences between fields on and fields off were .4 seconds or greater. The 10-Hz fields did not produce a reliable effect on behavior. Analysis of the EEG data showed a relative peak in power at the frequency of the fields (10 Hz and 7 Hz) for the hippocampus in all three monkeys. Similar peaks were seen less consistently in the amygdala and the centre median.

EFFECT OF LOW-LEVEL, LOW-FREQUENCY ELECTRIC FIELDS
ON EEG AND BEHAVIOR IN MACACA NEMESTRINA

R.J. Gavalas, D.O. Walter, J. Hamer, and W. Ross Adey

A series of preliminary experiments has been done in an
attempt to determine whether or not low-level electric fields
have an effect on behavior and/or patterns of electrical activity
in the brain of monkeys.

Very few studies of this kind have been done on either
animals or man. Experimentally produced changes in reaction time
in humans exposed to low-level, low-frequency (less than 12 Hz)
fields have been reported by Hamer[7] and Konig and Ankermuller[9].
Changes in human reaction time have also been observed under
low-frequency modulated magnetic fields (Friedman, Becker and
Bachman[6]). Wever[19] has described the modification of circadian
periods of activity in man under weak 10-Hz electric fields.
It was not known what kind of primate behavior, if any, would be
sensitive to field effects so that selection of a suitable
behavioral task was a first consideration. Earlier pilot studies
in this laboratory suggested that subjective time estimation
in humans was influenced by the presence of fields. In the
present study, we attempted to devise an analogous time estim-
ation task suitable for use with monkeys, so that electrodes
implanted deep in the brain could monitor brain electrical ac-
tivity throughout the experiments. It is known that scheduling
of reinforcements for a simple lever press can alter an animal's
rate of response, or the timing of that response, or both. In
the present study, monkeys were trained to press a lever under

a variation of a fixed-interval (timing) schedule of reinforce-
ment. Under this schedule there are no external cues or signals
presented to the animal; he must "time" his responses from the
occurrence of his own last response. It is a schedule which
has been widely employed in studies of animal behavior and has
been especially useful in detecting effects of small dosages of
drugs (Sidman[13]). It was expected that if there were an effect
of the fields it would be seen as a shift in the distribution
of the monkey's interresponse times.

Other questions of research strategy arose; it was not
obvious what brain structures, if any, would show an effect of
the presence of the fields. Nor was it clear what kind of
changes one might expect to see in the EEG--other than a possible
direct driving by the applied field--or how to assess such
changes. Consequently, an array of seven bipolar cortical and
subcortical electrodes were implanted in the first monkey. A
slightly different array was implanted in a second monkey and
electrode sites for the third monkey were selected on the basis
of results from the first two. Computerized spectral analysis
of the EEG was done and some special statistical tests were
devised to compare fields-on vs. fields-off changes in EEG.

Low-level (2.8 volts p-p) fields were used at two fre-
quencies, both within the range of frequencies usually evaluated
in EEG work (0-33 Hz). In some of the experimental runs,
10-Hz fields were used, to correspond to Hamer's earlier ex-
periments (Hamer[8]). In other runs, 7-Hz fields were used
because they were in the range of hippocampal theta (4-7 Hz), a
characteristic electrical activity of the brain that has been

shown to be important in orienting and discriminating responses
Radulovacki and Adey[10], Walter, Rhodes and Adey[17]).

Methods: Experimental Design, Behavioral Data Analysis, and
EEG Analysis.

I. Experimental Design.

Three pigtailed macaques were implanted with cortical and
subcortical bipolar electrodes, and were adapted to Foringer
monkey chairs. They were then trained to push a panel in front
of them on a fixed interval-drl (differential reinforcement of
low rates) limited hold schedule of reinforcement; (drl-h
schedule). The animal was gradually conditioned to wait 5 seconds
between pushes, and to push within a 2.5 second reward-enable
interval. If the animal pushed within the specified time
interval, he was rewarded with a squirt of apple juice. If he
pushed too early, or too late, he did not receive a reward, and
the timer recycled to the beginning of another 5 second interval.
The behavioral task was completely automated with logic modules
manufactured by B.R.S. Electronics. The monkeys were maintained
throughout training and experiments on a standard controlled diet
of monkey pellets, fruit, and restricted fluids. A liquid
reinforcer was chosen in order to eliminate chewing artifacts in
the EEG. The animal was trained until he was performing at a
high rate of accuracy (70-80%) and his performance was relatively
stable from one day to the next. All of the training was done
in an isolated and sound-proofed booth. Task electronics and
recording apparatus were in an outer room and the monkey's
behavior was continuously monitored on closed-circuit TV.

After the animal was performing well, his behavioral records

over a 24-hour period were examined to determine periods

of free responding during the day, and a four-hour segment of

time was selected for scheduling daily experimental runs. The

low-level (2.8 volts p-p), low-frequency fields were administered

by applying the voltage to two larger metal plates, 40 cm. apart,

which were fastened to the monkey's chair so that the head of

the animal was completely within the fields. Four-hour daily

tests with the fields on were randomly interspersed with four-

hour daily control runs without the fields. A total of twenty

such tests were done on the three well-trained monkeys. All

monkeys were given two tests with 7-Hz fields and two comparable

control tests without fields. Two of the three monkeys were

also given two tests with 10-Hz fields and two control runs

without the fields. EEG and behavioral data were continuously

monitored throughout all runs. In addition, EEG was monitored

in one monkey during two four-hour nonperformance runs (7-Hz

fields-on and fields-off) before he was trained to the drl-h task.

II. Data Analysis of Behavioral Changes.

Interresponse time data (IRTs) were collected by the computer

for each experimental run; each response of the animal was

tallied as a function of time elapsed since the immediately pre-

ceding response. Two-tenths of a second bin widths were used;

144 bins were counted and interresponse times greater than that

were tallied as 144 (28.8 seconds). Mean and standard devia-

tions were calculated for each four-hour run, and t tests were

used to compare IRT distributions for experimental runs and

the appropriate matched control runs.

III. Data Analysis of EEG Changes: Spectral Intensity,

Coherence, Discriminant Analysis.

EEG data was continuously recorded on a Grass polygraph
and an Ampex analog tape recorder. In the first monkey (J.)
EEG was recorded from the left hippocampus, right hippocampus,
right amygdala, midbrain reticular formation, right visual cortex,
left visual cortex and motor cortex. In the second monkey (Z)
EEG was monitored from the right hippocampus, left hippocampus,
left centre median, right visual cortex, and right amygdala.
In the third monkey (A.) records were taken of the electrical
activity of the right hippocampus, left hippocampus, right
centre median, left centre median, right amygdala, and left
amygdala.

Four sets of EEG data from comparable epochs from each
day's run were selected for computer analysis. A set of correct
(i.e., properly timed) responses was selected from the begin-
ning of the run and a second set from the end of the run;
similarly, a set of predominantly incorrect responses was sampled
from the beginning of the run and a comparable set from the end
of the run. Each epoch was approximately 80 seconds in length.
These epochs were spectrally analyzed in consecutive 10-second
samples and then averaged over the total 80 seconds.

The selected data epochs were converted to digital form
by the SDS 930 computer system of this laboratory and spectral
analysis of this data was performed, using the BMDX92 program
and the IBM 360/91 computer of the Health Sciences Computing

Facility. Spectral resolution was set at 2 Hz over the range 0-28 Hz for survey purposes. Spectra and coherences (Walter, Rhodes, Brown and Adey[18]) were averaged for each structure, within condition, and plotted; spectra were converted before plotting to relative units (by dividing by the total intensity in that structure in that condition) in order to compensate for day-to-day variations in total intensity; the result is called "percent power" at each frequency.

Spectral Intensity. A specialized statistical test for the effect of the imposed field on recorded activity was devised as follows. In the frequencies from 4-20 Hz, at least, the spectra were close to exponential in shape, in the absence of fields. If this were exactly true, the logarithm of the spectral curve would be a linear function of frequency, over this range. Then any activity contributed by the field would be above the line containing those points not at the field frequency (or its harmonics). Accordingly, we tabulated the statistic ("peak quotient") for the 10 Hz field.

$$\log_e(S_{10}) - 1/2\left[\log_e(S_{12}) + \log_e(S_8)\right]$$

When the field was at 7 Hz, more care was required. The 7-Hz signal appeared both in the filter band centered at 6 Hz and (to a lesser extent) in that centered at 8 Hz. We chose to test only the value at 6 Hz, and to compare it with the line based on 4 Hz and 10 Hz; thus, the peak quotient for the 7-Hz field became

$$\log_e(S_6) - \left[2/3\,\log_e(S_4) + 1/3\,\log_e(S_{10})\right]$$

The spectral estimates have a sampling distribution like chi^2/d.f., with d.f. calculated by the program (according to

formulas adapted from Blackman and Tukey[4]) as approximately 200
in our case. Thus, the natural logarithm of a single spectral
intensity has an approximately normal distribution, with
variance 2/d.f., and a coefficient of skewness of -0.1 (Abramowitz
and Stegun[1]). Our peak quotient statistic, then, is close to
normally distributed with variance .01. Its response to ap-
plication of the field in the two experiments for each animal
could be tested by the t-statistic, with the two fields-off
values providing the mean corresponding to the null hypothesis
of no effect of the field.

Coherence. An additional parameter calculated by the
spectral analysis program is the coherence between the imposed
field and the activity in each structure, as well as between
the brain structures themselves. It is essentially analogous
to the squared coefficient of correlation, and hence, a measure
to the linear predictability between the two wave forms, taking
into account spectral intensity, frequency and phase lag.
Although the purity of the imposed sinusoidal field invalidates
the usual distributional assumptions about the coherence statistic,
we felt these results might be suggestive.

Discriminant Analysis. In seeking for less obvious field
effects, we applied step-wise discriminant analysis (Anderson[2],
Rao[11]) to spectral and cross-spectral parameters, with the
exclusion of the frequency band containing the field frequency,
or else of that band and all bands containing any harmonics of
that frequency. Applications of this computer program, Discan
(based on BMD 07M, Dixon[5]) to spectral analysis of EEGs have

been described previously (Walter, Rhodes and Adey[17]; Rhodes, Walter and Adey[12]; Hanley, Walter, Rhodes and Adey[9]; Berkhout, Adey and Campeau[3]).

Results

Behavioral data. Consistent differences in interresponse time distributions were observed in the 7-Hz experiments. The 10-Hz field condition failed to produce a reliable effect on the behavior. For one animal (Z.) the mean interresponse time was unchanged by the 10-Hz field; responses were slightly faster (but not significantly so) in the replication. In animal J., interresponse times were faster in the first 10-Hz experiment and slower in the second.

Under the 7-Hz condition, however, rather large and consistent differences were observed in all animals. Animal Z. showed a shift in mean interresponse time toward shorter IRT's; the difference was approximately one-half second in the first experimental-control run. This finding was replicated in a second experiment (See figure 1) and these differences were highly significant statistically (p = .01 or better). In general, the whold distribution was shifted towards faster responses, while overall number of responses did not increase or decrease consistently. For the second animal (J.), the IRT mean shifted significantly in the direction of faster responses in the first experiment; however, this difference was not replicated in the second experiment. The third animal (A.), like the first, showed a shift in the direction of faster responses under the 7-Hz field. This difference was statistically significant

and was replicated in the second experiment. Percent of correct responses (those falling between 5 and 7.5 seconds) did not differ significantly under fields-on conditions for monkeys J. and Z.; monkey A., who had a large number of very long IRTs in the fields-off condition, showed gains of 16% correct and 21% correct when the fields were on. In summary, five of the six experiments showed a shift to significantly faster inter-response times under the 7-Hz fields compared with fields-off performance. All of these mean differences were .4 seconds or greater. Shifts in modal values also occurred in all 5 experiments and were all .2 seconds or greater. The distributions and means for all monkeys are shown in Figure 1. It may be observed that the overall output of responses and the variability of those responses differs considerably from monkey to monkey. Nevertheless, the direction of the mean shift under the fields is remarkably consistent and the size of the shift is relatively large.

EEG data: Visual inspection of the EEG data during the experiments did not reveal any marked effects due to the fields. An examination of the percent power graphs, however, revealed small peaks in power from some brain structures at the fields frequency, for epochs of predominantly incorrect responses near the end of the run. A sample of EEG data and percent power graphs is shown in Figure 2.

Peak quotients (as described in the methods section) were compared via t-tests for these epochs in fields-on versus fields-off conditions, for each animal and for each structure. (See Figure 3). In the first animal (J.), significant differences

were observed in the left hippocampus, the right hippocampus and the right amygdala for both the 7-Hz and the 10-Hz condition. In the third animal (A.), 7-Hz fields only were tested. Differences at the .01 level or better were observed in right hippocampus, left hippocampus, and left centre median. EEG records were also evaluated for this animal while he was sitting quietly and before he had been trained to do the drl-h task. Differences in peak quotients for 7-Hz fields-on vs. fields-off were observed in four of six structures tested: right hippocampus, right centre median, left hippocampus, and left amygdala.

Coherence measures between the 7-Hz sinusoidal wave form and the responsive EEG structures were always higher for the fields-on condition than for the fields-off condition. Sample measures are shown in Figure 4. Coherences between responsive brain structures did not reveal a consistent pattern of change.

No effects on EEG at non-field frequencies were visually noticeable, but the discriminant analysis program Discan (see Methods) was applied to the data of one animal (J.), and iden-tified strong driving (increased intensity and increased co-herences) at harmonics of the field frequency. Although such harmonic response is perfectly compatible with biological trans-duction (Walter and Adey[16], Van der Tweel and VerduynLunel[15]), it does not exclude artifactual transduction. Further appli-cation of Discan, this time excluding all bands containing any harmonics of the field frequency, still showed a clear discrim-inability of fields-on from fields-off EEGs, principally in that intensity was raised in the fields-on condition, even in non-harmonic frequency bands.

Discussion. The behavioral results suggest that imposing a 7-Hz field on the performing animal resulted in shorter interresponse times. Results with 10-Hz fields were not reliable. Experimental/control differences for the 7-Hz runs were statistically significant for five of six experiments, and these differences could be observed in all three monkeys. In spite of large differences in total output of responses from monkey to monkey, the shift in interresponse times was very consistent (towards faster responses) and rather large (.4 seconds or greater).

Increases in EEG intensity (peak quotients) at the frequency of the fields were observed in all three animals in the hippocampus, and less consistently in the amygdala and centre median. These differences were observed both in the 7-Hz and 10-Hz conditions. Coherences between the sine wave and responsive brain structure at the fields frequency were always higher in the fields-on condition.

The analysis of the EEG data presents special problems. The difficulty of isolating effects of biological transduction from those of transduction at the electrode/tissue-fluid interface is considerable, being almost parallel to the impossible question of "what the tree looks like when no one is looking at it." Nevertheless, the discriminant analysis program has provided preliminary evidence of subtle EEG changes at non-field frequencies that cannot be easily explained as electrode/tissue artifacts.

The concordance of evidence for a fields effect on behavior and on electrical activity of the brain is encouraging. We

intend to pursue additional demonstrations of these same kinds as well as others. One new technique to be applied is a frequency "sweep" from 5 to 20 Hz, with enough time spent at each frequency to allow coherence estimates to be reliably made there; our prediction is that, as occurred with wholebody vibration in the monkey (Walter and Adey[16]), and as seems to occur with sinusoidally modulated light stimulation in the human (van der Tweel and VerduynLunel[15]) there will be a band of incoherent driving. It may even be possible to establish some specific non-linear model, along the lines successfully pursued by Spekreijse[14] for the visual system.
