DEVELOPMENT OF CATHODIC ELECTROCATALYSTS FOR USE IN LOW TEMPERATURE H₂/O₂ FUEL CELLS WITH AN ALKALINE ELECTROLYTE

CONTRACT OBJECTIVES

The research under contract NASW-1233 is directed towards the development of an improved oxygen electrode for use in alkaline H_2/O_2 fuel cells. The work is being carried out for the National Aeronautics and Space Administration, with Mr. E. Cohn as technical monitor. Principal investigators are Dr. J. Giner and Dr. J. Parry.

ABSTRACT

4

In the first phase of this program (section 1 of this report), a survey was carried out on the intrinsic activity of the transition metals, selected transition metal alloys and intermetallic compounds, and transition metal carbides, nitrides, borides and silicides for the electrochemical reduction of oxygen. Subsequently, alloy compositions known to be active were studied in detail. These included (section 2) gold alloys of the precious metals and silver magnesium alloys. Measurements made on finely divided catalysts and compounds of group VIII metals prepared by the Eureau of Mines are described in section 3, while catalysts prepared for life testing and the longevity tests are given in section 4. A coprecipitated platinum gold black was discovered which shows higher performance than platinum. Section 5 is the mathematical treatment of porous PTFE-bonded electrodes. A new model is proposed and the results indicate the possibility of very high power density electrodes.

SECTION 1: SUMMARY AND CONCLUSIONS

Survey of the Intrinsic Activity of Catalysts for the Cathodic Reduction of Oxygen (Solid Electrodes)

A summary of the data obtained in the survey is presented in Table II; the principal conclusions to be made from it are as follows:

A. The Elements

The activity for the reduction of O_2 was $Pt \sim Pd > Au \sim Ag > Mn > C \approx Os$. Of the remaining elements Fe, Re, Ir, and Rh were active below +675 mv; Ni, Ti, and Cu were active below +360 mv on the DHE scale (DHE \approx -30 mv vs. RHE).

Metals most active for oxygen reduction were generally those with easily reduced surface oxides. The principal exception was manganese: A substantial O_2 reduction current was observed on MnO₂ at about +900 mv.

TEN ATTACK

B. Alloys and Intermetallic Compounds of Transition Metals

The materials examined were alloys of transition metals. They are discussed under four groupings — alloys of (1) platinum, (2) nickel, (3) Ti, Zr, Hf, and (4) Ta.

1. Platinum Alloys

Alloys of platinum with base metals were generally less active than platinum, although a number of alloys equalled platinum in activity, e.g. Pt_2Ta and PtMn.

Alloys of platinum with metals that corroded in the pure state often developed a roughened or etched surface. However, the extent of corrosion was far less than that for the pure, base metal. For example, Pt₂Nb corroded at a substantially lower rate than Nb; similarly, Pt₃Co did not form the surface oxides found with pure cobalt. Alloys showing corrosion (e. g. PtNb) may show a high apparent activity because of surface roughening.

2. Nickel Alloys

Of the nickel-based metal alloys studied, only those with manganese and cobalt were significantly active for the reduction of O_2 . In the former system the activity is associated with manganese. The activity of NiCo₂ is probably due to the formation of a surface layer of nickel-cobalt spinel. The activity is enhanced by holding the starting potential above +1200 mv, where Co⁺³ is formed. Apparently Co⁺³ is reduced to Co⁺² below +750 mv and the activity noted above this potential disappears below +750 mv. Returning the electrode to high potentials restores its performance. This effect was not observed for pure cobalt because of excessive corrosion current.

One of the more interesting characteristics of nickel alloys is the effectiveness of nickel in suppressing corrosion of the alloyed constituents. These effects were observed for alloys of at least 50 wt % nickel and either Mn, Co, Al, Nb, or Mo.

ii

3. Titanium, Zirconium, and Hafnium Alloys

The corrosion behavior of these alloys was similar to that of nickel. No pronounced enhancement of O_2 activity was noted for alloys containing base metals. In fact, the small amount of activity associated with nickel was inhibited in Zr_2Ni and suppressed in TiNi₃.

The activity of TiPt_3 was less than that of platinum, while Ti_3Au was more active for the reduction of O_2 than gold, being comparable to platinum. The surface area of Ti_3Au increased with time, apparently yielding a surface having a higher Ti/Au ratio than the bulk material had. In spite of the higher surface concentration of non-noble metal, activity of the sample also increased. ZrAu_3 , richer in gold than is Ti_3Au , showed a lower activity than gold itself and a stable surface.

4. Tantalum Alloys

The performance of alloys of tantalum showed very little interaction between the metals; i.e. the corrosion and O_2 activity were approximately what was expected from a mixture of the pure metals. TaPt₂ and TaPd₃ are essentially as active as platinum and palladium, respectively.

C. Carbides and Nitrides of the Transition Metals

The carbides and nitrides showed, in general, greater activity than the parent metal; even when the metal itself was inert (e.g. Zr, Hf, TaCr) the carbide showed some activity for O_2 reduction. The highest activities were observed for TiN, VC, Fe₂C, Ni₃C. The latter two materials are discussed in detail in section 3.

D. Borides and Silicides of the Transition Metals

The borides and silicides were characterized by rapid corrosion at O_2 reduction potentials. Exceptions were Ni_2B and Ni_3B , which experienced slight corrosion, and Pt_2B , which was resistant. The activities of these three materials were no greater than those of the parent metals.

E. Silicon Carbide Single Crystals

The $6H-\alpha$ silicon carbide single crystal is of interest since opposite faces are monatomic and present either silicon or carbon atoms on polishing. The behavior of these faces would be expected to be similar or different, depending on the relative importance of continuum or atomic properties in the catalytic activity of this crystal. The two surfaces behave differently. Notably the first reduction current observed on the carbon side occurs at 525 mv vs. RHE and on the silicon side at 375 mv, suggesting that continuum factors are not dominant in this case.

F. <u>Titanium</u>, Nonstoichiometric TiO₂

The initial survey on solid electrodes showed Ti_3Au to have an activity comparable to platinum. In finely divided form the Ti_3Au intermetallic corroded rapidly and subsequently demonstrated low activity, probably due to the formation of TiO_2 . Two approaches were adopted in an attempt to take advantage of the activity displayed by titanium gold intermetallics. One was a more extensive study to understand the electrochemistry of titanium and TiO_2 better, particularly in its nonstoichiometric form which has an electronic conductivity several orders of magnitude greater than the stoichiometric form. The second approach was to look at other alloys of titanium and gold.

The studies of titanium and nonstoichiometric TiO_2 showed that thin films of the nonstoichiometric oxide on titanium will cathodically reduce O_2 at potentials of 550 mv, 220 mv more positive than on the passive stoichiometric TiO_2 film normally formed. Measurements on single crystals of nonstoichiometric TiO_2 showed that the nonstoichiometric forms of reasonable conductivity (e.g. $\text{TiO}_{1.8}$) are stable (i.e. they do not revert to TiO_2 stoichiometry) under the experimental conditions of oxygen reduction. However, titanium powder, oxidized under conditions that should give rise to a nonstoichiometric oxide, produced an electrode of high ohmic resistance and negligible activity.

iv

SECTION 2: SUMMARY AND CONCLUSIONS

The Activity of Gold Alloys of Precious Metals and Silver Magnesium Alloys (Solid Electrodes)

L

A. Gold Alloys of Ag, Pd, and Pt

The rate of oxygen reduction was measured on gold, platinum, palladium and silver, and the alloys Au/Pd, Au/Pt, and Au/Ag at 10% increments of composition. The activity of the Au/Ag alloys decreased progressively as the silver content was increased. The Au/Pt alloys showed an almost constant activity over the whole composition range; the Au/Pd alloys, however, showed a broad maximum of activity (i. e. greater than that of the Au/Pt alloys) over the composition range. The order of activity was Au/Pd > Au/Pt > Au/Ag. For the 1:1 alloys the following potentials (E_{50}) were recorded at i = 50 μ a/cm²: Au/Pd - 926 mv, Au/Pt - 878 mv, Au/Ag - 856 mv, all vs. RHE. An interesting feature of the results is that at 25°C palladium (E_{50} = 922 mv vs. RHE) is more active than Pt (E_{50} = 880 mv vs. RHE). At 75°C these figures were 915 mv for Pd and 903 mv for Pt. In other words at 75°C and 50 μ a/cm² Pd was more active (12 mv less polarization) than Pt.

B. Silver Magnesium Alloys

The enhanced intrinsic activity claimed in the literature for Ag 1.5% Mg alloys compared with pure Ag was not confirmed. The higher activity that we measured for the alloy was directly related to an increase in surface roughness.

SECTION 3: SUMMARY AND CONCLUSIONS

Preparation and Testing of Finely Divided Catalysts

A number of materials tested as solid electrodes were prepared as finely divided powders: Pd-Au alloys, Pt-Au, Pt-Ag, Pt-Os, and Ti_3Au . Other materials were tested only as powders. All of the materials were tested as plastic bonded electrodes in the floating electrode cell at 75°C, 35% KOH, for oxygen reduction activity.

Many preparations of Pd-Au were made in which the preparative method and alloy composition were changed. The formaldehyde reduction process for making the alloy blacks gave the best results and the 70% Pd alloy was better than other compositions. The Pt-Au and Pt-Os were also made by formaldehyde reduction. Pt-Ag electrodes were made from m.x-tures of commercial Pt and Ag_2O .

Many preparations of titanium gold, Ti₃Au and TiAu were attempted. Some of these were moderately successful, but the final composition of the powder is believed to be almost pure gold, due to the leaching process involved.

Thirty two samples of Ni₃C were also prepared (in addition to the Bureau of Mines' preparations). Three of these were moderately successful, i.e. about 100 ma/cm² at 750 mv vs. RHE.

Interstitial compounds of Fe, Ni and Co in finely divided form were prepared by the Bureau of Mines. These were made up as plastic bonded electrodes and tested at Tyco in 35% KOH at 75°C for activity as O_2 fuel cell electrodes. The activity observed is summarized in Table XV The best performances observed in terms of current at 600 mv were iron carbide -32 ma/cm^2 , iron nitrocarbide -68 ma/cm^2 , iron carbonítride -3 ma/cm^2 , nickel carbide -94 ma/cm^2 , nickel cobalt carbide -125 ma/cm^2 , nickel nitrocarbide -68 ma/cm^2 , and nickel cobalt nitrocarbide -49 ma/cm^2 . Of the nickel cobalt materials the pattern of activity was 3 Ni/Co > Ni/Co > Ni/3 Co. All the cobalt carbide samples tested corroded rapidly. The level of activity of nickel

vi

carbide did not compare favorably with samples of nickel carbide (290 ma/cm^2) and nickel cobalt carbide (350 ma/cm^2) prepared by acetate decomposition in the laboratory. The most likely explanation for this difference is variation in the physical characteristics, particularly the porosity of the catalyst. Carbides and nitrocarbides of Raney alloys of nickel and cobalt with silver, gold and palladium showed greater activity (up to 180 ma/cm^2), but this was generally less than that observed for the uncarbided alloy, e.g. NiAuPd which gave a current of 315 ma/cm^2 at 750 mv.

The level of activity observed with the interstitial compounds of iron and nickel prepared by the Bureau of Mines (excluding those containing a precious metal) does not yet meet the requirements of a practical fuel cell catalyst. Nickel and nickel/cobalt carbides have demonstrated high activity, but reproducibility in terms of good electrode performance was not always obtained. If high activity nickel carbide catalysts could be prepared consistently and with reasonable electrode life, these materials would constitute catalysts of practical interest even though their performance is some 100 mv below that of platinum.

SECTION 4: SUMMARY AND CONCLUSIONS

Catalyst Life Testing

đ

Twelve of the materials tested as floating electrodes were life tested for times ranging from 500 to 3000 hours. The materials tested were as follows:

American Cyanamid Pt AB-40 (system reference)

TYCO Platinum (electrode fabrication reference)

Pt-Au 70/30 Pt-Ag 30/70 Pt-Os 80/20 Pd-Au 40/60 Pd-Au 50/50 Pd-Au 50/50 Pd-Au 70/30 Pd-Au 60/40 + 50 wt % Ag₂O Au-Pt-Pd (B. O. M.) Ag-Pt-Pd (B. O. M.) Ni₃C (B. O. M.) Ni₃C (TYCO)

The best results were obtained with Pt-Au 70/30, Pd-Au 40/60, and Pt-Ag 30/70. The Pt-Au alloy is particularly promising in that it showed a higher performance level than platinum at half the catalyst loading of the AB-40 electrode. The Pd-Au is also interesting in that there was no obvious performance loss that could be attributed to corrosion of Pd even after 3000 hours of operation.

SECTION 5: SUMMARY AND CONCLUSIONS

A Mathematical Treatment of the Porous PTFE Bonded Electrodes

A model for the Teflon-bonded electrode which differs considerably from the widely accepted Thin Film and Simple Pore models is proposed and analyzed.

In a Teflon-bonded electrode, the catalyst particles form porous (and electronically conductive) agglomerates which, under working conditions, are flooded with electrolyte. The catalyst agglomerates are bound together by Teflon which creates hydrophobic gas channels. As current is drawn from the electrode, reactant gas diffuses through the gas channels, dissolves in the electrolyte contained in the agglomerates and, after diffusing a certain distance, reacts on available sites of the catalyst particles.

The column of flooded agglomerates has been approximated in the mathematical treatment by a porous cylinder, perpendicular to the surface of the electrode. The catalyst particles and electrolyte in the column were considered to be homogeneously dispersed as a continuum. During operation, gas arrives at the cylinder in a direction perpendicular to its axis and diffuses to its center along the radius, with reaction on catalyst particles in the diffusion path. Ionic current is conducted in a direction parallel to the cylinder axis.

The results obtained with this model differ considerably from the results obtained with other published models. Thus, while the Thin Film Model and its variants predict that only a small fraction (1-10%) of the catalyst is utilized during operation, analysis of our model shows that under the studied conditions (O₂-reduction, i $\simeq 200 \text{ ma/cm}^2$, 20 mg Pt/cm², 35% KOH and 80°C), it is possible to obtain almost 100% utilization of the catalyst. This is a consequence of a very small iR-drop between front and back of the electrode. For example, at 350 ma/cm² this iR-drop is typically only about 10 mv.

ix

Because high utilization of catalyst can be obtained with relatively thick electrodes, our work shows that high power density $(amps/cm^2)$ electrodes can be built.

The assumptions made in the treatment and the limitations of the model are discussed briefly. It is shown that with the present assumptions our model does not apply to reactions with higher i_0 (such as the H₂-electrode), and modifications of the model are necessary.

SECTION 1

SURVEY OF THE INTRINSIC ACTIVITY OF CATALYSTS FOR THE CATHODIC REDUCTION OF OXYGEN (SOLID ELECTRODES)

I. INTRODUCTION

The selection of alloys for experimental investigation as electrocatalysts for oxygen reduction must be carried out in a systematic way. Random selection is a question, ble procedure, since the number of possible systems is extremely large. For example, even if one restricts the choice to about 30 transition metals that are generally good catalysts, there are about 400 binary systems, 4,000 ternary systems, 28,000 quaternary systems, and so on, for a total of about a hundred million systems. If we consider that, in addition, there are distinct intermetallics and that even solid solutions of different concentration may have qualitatively different properties, it is clear that in the available time we can study only a tiny fraction of the possible compositions.

The intrinsic factor which determines the reactivity of an oxygen electrode is its atomic composition and the subordinate crystal structure. The composition ultimately determines both the desirable properties (viz. electrocatalytic activity for reduction of oxygen) and the undesirable properties (viz. corrosion or other time-dependent failure mechanisms which limit the efficiency or life of the electrode). The electrode activity may be an inherent characteristic of the pure electrode surface, or it may be conditioned by reactions with the electrolyte, e.g. through specific adsorption or ions.

Previous work on catalysts has been treated within a theoretical framework based on a consideration of two extreme points of view concerning the source of surface activity. According to one view (which can be called

1 -

the "atomic approach"), the reactivity is determined by the intrinsic chemical properties of the individual surface atoms and is only slightly influenced by the neighboring atoms in the crystal bulk. The other extreme view (which can be called the "continuum approach") is that reactivity is determined primarily by the electronic energy states of the material as a whole, with the specific atomic chemistry being secondary. This approach has been used extensively to interpret chemisorption and catalysis on transition metal alloys where the surface activity has been correlated with d-band occupancy.

The oxygen reaction is admittedly a more complex process, the mechanism of which (i.e. the precise sequence and relative rates of the various elementary steps) still remains unresolved⁽¹⁾. However, there is ample evidence for the existence of a special kind of oxygen-metal interaction during the electrolytic reduction of oxygen, even if knowledge of the precise nature of this interaction is scanty.

There is also little doubt that the disruption of the oxygen-to-oxygen bond is the slowest step in the over-all process and that hydrogen peroxide appears as an intermediate or by-product during reduction in alkaline solutions. Without going into the details of the reaction, we can thus safely assume that (a) electronic factors play an important role in the kinetics and (b) geometric factors are probably also involved in the catalytic breaking of the oxygen bond.

Catalysts were selected with both the "continuum" and "atomic" approaches in mind. Alloys of noble metals (Pt, Au) – which are good catalysts for O_2 reduction – with base metals were investigated, as well as alloys containing only base metals. The materials examined encompass a variety of crystal types; a partial listing is given in Table I. The validity of the continuum approach to the electrocatalysis of oxygen reduction would be established by alterations on the noble metal activity through alloy formation and/or by the development of high activity through alloying of low activity base metals.

II. EXPERIMENTAL

A. Introduction

A convenient method of testing a material for corrosion resistance and catalytic activity was to use it as a solid ingot. As such, it could be mounted in an alkali resistant resin and tested potentiostatically as a rotating disc electrode run consecutively in N_2^- and O_2^- saturated KOHsolution.

By potentiostatic measurement of the corrosion current under an inert atmosphere, it was possible to measure the corrosion rate over the whole potential region relevant to an oxygen electrode.

The advantages of this method are that the samples can be prepared with relative ease and have well-defined surfaces. They could therefore be tested unequivocally for corrosion and for O_2 -activity under welldefined transport conditions (Levich equation). The main disadvantage of the method is the sensitivity of the electrode, with its low roughness factor, to poisoning by impurities. This disadvantage is minimized by the high electrode potential at which O_2 is reduced and by continuous surface renewal due to the small corrosion current present in most cases. The low concentration of surface defects on solid electrodes, in contrast to that on dispersed electrodes, may lead to lower specific activity, but this difference is probably irrelevant in a comparative study of the relative activity of a series of materials.

B. Testing of Solid Ingots as Rotating Discs

1. Preparation of the Disc Electrode

Carefully weighed mixtures of pure elements were arc-melted in a furnace with six water-cooled copper heaters (each one-inch in diameter), using a tungsten tip under an argon atmosphere. A Ti getter was fired before each run in order to eliminate traces of O_2 . A maximum of six ingots weighing 5 to 10 grams could be obtained in one run.

WYANT AVERAGE

If the alloy or compound was formed peritectically (i.e. during solidification the composition of the solid phase differs from the composition of the liquid phase), the ingot was annealed, generally overnight, at a convenient temperature. If the alloy or compound was formed congruently (i. e. the solidifying phase had the same composition as the molten phase), the ingot could be used without any subsequent thermal treatment.

The ingots were button shaped when removed from the furnace and were cut with a boron carbide or chromonel saw in order to expose two parallel, flat, circular faces. One part of the sawed button was used for metallographic analysis, according to standard procedures.

The part of the button with the two parallel, flat, circular planes was incorporated as shown in Fig. 1a with "Koldmount," (an acrylic resin – including methylmethacrylate monomer – used for metallographic work, which erroded less than 0.05 mg/cm² in 2N KOH at 80°C over a period of 80 hrs). This arrangement, besides isolating the electrical contact to the electrode from the electrolyte, also constituted an ideal configuration for controlling precisely mass transport to the electrode.

Electrical contact to the button was made by screwing a metal rod down on a spring-loaded contact in the threaded shaft of the Koldmount. The rod, spring, and contact were gold-plated and the rod was covered with heat shrinkable Teflon tubing (Fig. 1a). The electrode assembly was mounted in a Sargent 600 rpm synchronous motor designed for voltammetry with solid electrodes. Contact between the stirring rod and the fixed lead was made by dipping a wire into a pool of mercury in the hollow top of the rod.

A series of ductile materials was also tested in a demountable assembly described by Stern and Makrides⁽²⁾, with only Teflon and glass exposed to the solution (Fig. 1b). Ductile materials tested in both electrode assemblies gave basically the same results. This confirms that the acrylic resin used in the rotating disc had no poisoning effect on the results.

- 5 -

2. Test Cell

The cell shown in Fig. 2 was used. In this cell all the frits were eliminated since they dissolve in caustic solution. The lack of a frit between working and counter electrodes did not introduce a significant error, since during the cathodic oxygen reduction (with oxygen saturated solution) only oxygen was evolved at the counter electrode. The hydrogen evolved at the counter electrode during the corrosion test (N₂-saturated solution) which could dissolve and reach the working electrode was largely swept by nitrogen and therefore did not contribute significantly to the measured current.

The reference electrode was a Dynamic Hydrogen Electrode (DHE)⁽³⁾ which under the cell-operating condition adopted a potential 30 mv \pm 5 mv negative to the RHE.

The temperature of the cell was regulated $\pm 0.5^{\circ}$ C by a heating mantle and a regulator with a temperature sensor inside the electrolyte. A temperature of 75°C was selected for the experiments.

The electrolyte concentration was set at 2M KOH after preliminary experiments with 35% (8.4 M) KOH. This concentration had a more favorable transport factor (D x C) than 8.3 M KOH solutions used in fuel cells. Since the screening electrolyte was milder, the chances of missing a possible catalyst were reduced.

3. Electrochemical Measurements

i(E)-curves were generated by imposing a linear potential scan on the working electrode by means of a slow linear potential signal to a Wenking potentiostat. The slow function generator was constructed with two standard batteries, two 10 turn, 10 K potentiometers, and a synchronous motor (Insco Corp., Groton, Mass.). The motor has a basic speed of 4 rpm and six gear ratios of 1:1, 2:1, 5:1, 10:1, 20:1, and 50:1. By changing these gear ratios and the peak voltage, scanning rates from 10 mv/min to 800 mv/min could be obtained. For the initial routine screening, a rate of 50 mv/min was selected.

- 8 -

The current-potential curve was recorded directly on an x-y recorder. Current-time curves at constant potential for relatively long times could be recorded on the same recorder by using the slow function generator to feed the y-axis of the recorder.

Before an activity test experiment, the corrosion current under inert gas (N_2) was measured at a series of potentials. This corrosion current had to be measured with stirring in order to subtract it quantitatively from the O_2 reduction current. It was also measured without stirring in order to apply the results to a practical electrode. Also, the possibility of a decrease of the corrosion rate with time had to be investigated. As long as the corrosion current was small compared with the expected O_2 -current, the O_2 -curve was run, even if the corrosion rate was higher than useful for a practical cell.

In order to ascertain whether an observed performance represented the intrinsic activity of a material and not a mere increase of the surface area, the real surface area of the electrode had to be estimated. The only practical method of doing this during screening of a large number of flat electrodes was by measuring the double layer capacity of the electrode.

For the capacity measurements a method was selected in which a triangular wave of 50 cycles/sec and a peak-to-peak voltage of 100 mv (i. e. a sweep rate of 10 volts/sec), biased by a convenient dc voltage, was fed to the signal input of the potentiostat. The dc voltage was selected so that Faradaic currents were avoided. If the electrode behaves as a perfect capacitor (no Faradaic or ohmic resistance), the small triangular potential wave is transformed into a square current wave, with a peak-to-peak value which is proportional to the electrode capacity and therefore to the real surface.

C. Procedure

The following procedure was used for routine screening:

(1) \underline{N}_2 Saturation

and the state

A freshly prepared 2M KOH solution was saturated with pure nitrogen for at least 45 minutes. The electrode was kept inside the cell but not exposed to the electrolyte until N_2 saturation was complete.

- 9 -

(2) Corrosion i(E)-Curve

The electrode was introduced into the solution at a potential of E = 0 mv. The potential scan was initiated within a minute at a rate of 50 mv/min and 600 rpm rotation. The potential scan was reversed between E = 0.8 volt and E = 1.23 volts, depending on the extent of corrosion in this range. If there was a high corrosion rate at the lower potentials, higher potentials were still investigated since there could be a region of passivation in the potential range of interest.

At several points of the i(E)-curve, stirring was stopped for 1 or 2 minutes without stopping the potential sweep (in order to observe the effect of stirring on corrosion).

(3) Measurements of the Double Layer Capacity

At several points in the i(E)-curve under N₂, the recording was interrupted and a double layer capacity measurement was made as described above.

The electrode potential was never left uncontrolled in order to control the history of the electrode from the moment it was immersed in solution. If, in addition to the i(E)-curve, the electrode had to be left for some time at a known potential, the time at this potential was kept as short as possible and noted. The electrode was removed from the solution during extended periods of inactivity, and any attached electrolyte was removed by rotating the electrode in the gas phase for a short time (about half a minute).

(4) $\underline{O_2}$ -Saturation

If the corrosion current was within tolerable limits, the test for O_2 -activity was carried out. The electrode was removed from the system and repolished, and the solution was saturated with O_2 (at least 45 min).

(5) <u>i(E)-Curve for O_2 -Reduction</u>

The repolished sample was introduced into the electrolyte at a high, passive potential where possible, but below any current wave

- 10 -

(usually between 0.8 volt and 1.23 volt), and the i(E)-curve was initiated in the direction of decreasing potentials. At E = 0, the direction of the potential sweep was reversed.

(6) Measurements of the double layer capacity in the region of the limiting current were necessary when doubts existed about the real surface increase during recording of the i(E)-curve.

(7) After recording the i(E)-curves, a micrograph of the electrode surface was taken and the sample was filed for subsequent study.

(8) The data presented in tabular form are corrected to the reversible hydrogen electrode (RHE) in the same electrolyte by subtracting 30 ± 5 mv from the recorded potentials (DHE).

D. Presentation of Data

Table II lists the following information for the transition elements and alloys and intermetailic compounds: $E_{\frac{1}{2}}$, the half wave potential; E_2 , the potential at which cathodic current was first observed; i_L , the limiting current density; and C, the double layer capacities of the electrode. The significance of these measurements in defining the activities of a catalyst is established below. The detailed results from which these figures were derived were presented in the Fourth Quarterly Report⁽⁴⁾. Comment is also made in Table II on the corrosion (anodic currents) observed for the electrode measured in the absence of O₂.

The reduction of oxygen is an irreversible process, and in the absence of concentration polarization, the current potential curve is described by

$$i = i_{0} \exp \left(\frac{\alpha z F}{RT} \eta\right)$$
(1)

WARE A FRANCE A

where i_0 is the exchange current, α the transfer coefficient, $z = \frac{n}{\nu}$ where n is the number of electrons involved in the electrode reaction

and ν the stoichiometric number, F is Faraday's constant, R the gas constant, and T the absolute temperature.

If, in addition to activation polarization, concentration polarization appears due to O_2 depletion at the electrode, equation (1) converts to:

$$i = i_0 \left(\frac{C^E}{C^B}\right)^{Z'} \exp\left(\frac{\alpha z F}{RT}\right) \eta$$
 (2)

where C^E and C^B are the concentrations of oxygen at the electrode and in the bulk of the solution, respectively, and z' the stoichiometric factor⁽⁵⁾ for the oxygen molecule in the reduction reaction.

Equation (2) can be rewritten as

$$\eta = \frac{RT}{\alpha z F} \ln \frac{i}{i_0} + \frac{z' RT}{\alpha^2 F} \ln \left(\frac{C^B}{C^E}\right)$$
(3)

It can be easily demonstrated that in case of diffusion-controlled limiting current (as is the case in most of our experiments), at the half wave potential (i.e. when $i = i_{d/2}$) $C^E = \frac{C^B}{2}$.

Equation (3) can then be rewritten as

$$\eta = \eta_{act} + \frac{z'RT}{\alpha z F} \ln 2$$
, or at $T = 75^{\circ}C$ (4)

$$\eta = \eta_{act} + \frac{z'}{\alpha z} \quad 0.018 \text{ (volt)} \tag{5}$$

Thus, for electrodes with similar hydrodynamic conditions (as exist in our experiments) at the half wave potential of a diffusion limited wave, $i = \frac{1}{2}i_L = const$ and the overvoltage $(\eta_{\frac{1}{2}} = E_{\frac{1}{2}} - E_{0})$ is equal to pure activation polarization plus a small numerical term. This term depends on the transfer coefficient, stoichiometric factor, and stoichiometric number.

It is apparent that the half wave potential is a very appropriate quantity for comparing catalysts studied under identical hydrodrynamic conditions, since the normalization of the current to this potential is not subject to errors made in the measurement of electrode area.

In this system there are two complications which limit the rigor with which such a comparison can be made:

(1) <u>The passivating effect of oxides and chemisorbed</u> <u>oxygen</u>. Because of this effect, it is frequently found that above a given potential no current is seen, while below the potential at which the "oxide" is reduced, a very steep (purely diffusion controlled) wave appears. It is therefore possible that electrodes with little "oxide passivation" but large overvoltage due to other causes show a more negative half wave potential than do electrodes with very steep waves but with an "oxide inhibition" at low polarizations.

(2) The formation and accumulation of HO_2 by partial reduction of O_2 during the following reaction sequence:

$$O_2 + H_2O + 2e^- \rightarrow HO_2^- + OH^-$$
(6)

$$HO_2^{-} + H_2^{-}O_2^{-} + 2e^{-} \rightarrow 3OH^{-}$$
 (7)

It is possible in principle that an electrode with completely reversible step (6) and very irreversible step (7) (i.e. with a very low half wave potential for the 4-electron O_2 -reduction over-all wave) shows much more negative half wave potential than an electrode with less reversible reaction (6) but a more reversible reaction (7).
In order to eliminate this uncertainty, we have included in the tabulation the initial potential, i.e. the potential at which a net cathodic current is observed. This value is, at best, semiqualitative since it is dependent on the sensitivity of the ammeter and the presence or absence of corrosion current. Even with these limitations, it is a good complement to the half wave potential for comparing catalyst performance.

III. <u>RESULTS</u>

A. Transition Metals and Intermetallics

Table II presents all the data accumulated on the activity and corrosion resistance of the elements of the transition series and of intermetallic and interstitial compounds. The intermetallic compounds are listed alphabetically for each component. Supplementary Tables III to IX group the materials in terms of activity, corrosion resistance, etc., and are discussed in detail below.

The first group (Table III) comprises those transition elements that show activity for O_2 reduction above + 800 mv.

TABLE III

Transition Metals Active for O_2 Reduction Above + 800 mv

| Mn | Ag |
|----|-----|
| | Au |
| Pd | (C) |
| Pt | Os |

The performance curves indicate the order of activity (based on initial potential): Pt \approx Pd > Au \approx Ag > Mn > C \approx Os.

Of the remaining elements, Fe, Re, and Ir are active below +675 mv; Ni, Ti, and Cu are active below +360 mv.

A parallel grouping of the metals can be formed according to whether oxygen is reduced on an oxide or on "bare" metal. This correlation is shown in Table IV.

- 24 -

TABLE IV

Oxygen Reduction Activity vs. Surface Composition

| Oxide Surface | Metal Surface |
|---------------|---------------|
| Ti | Pd |
| Nb | Pt |
| Fe | Ag |
| Mn | Au |
| Ni | Cu |
| * | |

The performances of the transition metals are summarized in Table V according to position in the periodic table, in Table VI, according to the potential region of activation controlled current, and in Table VII according to $E_{\frac{1}{2}}$ and $E_{\frac{1}{2}}$ values.

The most active elements are those for which the metal itself catalyzes the O_2 reduction process. The low limiting currents and the slope of the performance curves for Fe, Ti, and possibly Ni and Re indicate that these materials have a low activity for the decomposition of HO_2^{-1} . Nb also shows a two-step reduction; however, some ambiguity is introduced by corrosion.

Manganese dioxide is the one oxide which shows activity for oxygen reduction at high potentials.

* Apparent insoluble oxide

10

- 31 -

In a number of cases, the observed corrosion behavior was other than that predicted by thermodynamics. Consider the following specific examples:

a) Vanadium corroded at negative potentials, presumably due to the formation of HV $_2O_5$. A slight passivation occurred at $\neq 200$ mv; the predicted transition to V_2O_5 or $H_3V_2O_7$ at about 600 mv was not observed.

b) Niobium is reported to be covered by an insoluble cxide at positive potentials. However, corrosion of niobium was observed above + 250 mv, presumably because of a soluble reaction product.

c) The formation of soluble WO_4^{-1} is predicted to occur at negative potentials. However, the formation of a soluble corrosion product was not observed below +200 mv.

The remaining transition elements show some activity for O_2 reduction. Table IX lists elements which catalyze O_2 reduction above + 800 mv.

The borides, silicides, carbides, and nitrides of the transition metals were surveyed for their corrosion behavior and their activity for catalyzing the electrochemical reduction of oxygen.

The performances of materials within each grouping is discussed in terms of modifying the properties of the parent transition metal.

In a later section of this report, we discuss a more detailed study of highly dispersed carbides, nitrides, nitrocarbides, and carbonitrides of Fe, Ni, and Co. The data presented below are, except where noted, for solid electrodes.

B. Nitrides and Carbides

(1) Ti, TiN, TiC

A slight anodic corrosion current is observed for titanium. This current is much less for TiN even though the surface area of the nitride is much greater, as indicated by the capacitance (540 μ f/cm²). Substantial corrosion of TiC is observed above +830 mv. Judging from the absence of a passivating current, the reaction product is either partly soluble or porous.

The O₂ reduction activity of TiN is substantially higher than that of Ti. The current-potential curve has two waves, implying a difference in rate for O_2 and HO_2^- reduction noted for oxide coated metals. This material was also studied with a graphite counter electrode to eliminate the possibility of contamination of TiN by dissolved platinum. No difference in activity was found.

- 32 -

TiC is slightly more active than titanium and some O_2 reduction current is noted at + 820 mv. However, its performance is less than that of TiN. Some of this could be ascribed to the large difference in surface area.

(2) Zr, ZrN, ZrC.

As noted previously, Zr does not corrode or reduce O_2 over the potential range studied. ZrN shows a slight activity and possibly corrosion at potentials above +600 mv.

Corrosion is not observed for ZrC; the material shows cathodic current for O_2 reduction below + 400 mv.

(3) Hf, HfN, HfC.

Hafnium, like Zr, is inert over the potential range studied. The low capacitance (2 μ f/cm²) is consistent with an insulating oxide film. HfN is also essentially inert although there is a slight indication of activity below + 500 mv.

HfC shows an anomalous anodic current peak at + 630 mv. O_2 reduction is observed at potentials less positive than + 500 mv.

(4) <u>V, VN, VC.</u>

Vanadium corrodes under the conditions of the experiment, presumably with the formation of a soluble product. Anodic corrosion current is observed for VN above +180 mv, and a small amount of oxygen activity is observed below + 180 mv. These corrosion reactions are further suppressed in VC. Anodic current is observed only above +820 mv; the low capacitance (60 μ f/cm²) at + 600 mv is consistent with a stable surface. Cathodic O₂ reduction current is observed below this potential.

(5) Nb, NbN, NbC.

Niobium corrodes above + 170 mv, but is also active for O_2 reduction; a net cathodic current was observed below + 270 mv. The corrosion behavior of NbN is similar to that of the metal; the O_2 activity may be less, although this point is difficult to establish because of the corrosion current.

NbC is more resistant to corrosion than is the metal; anodic current is observed only above + 600 mv. Reduction of oxygen is observed below this potential; as with the other carbides studied, two waves are present.

- 33 -

(6) Ta, TaN, TaC.

n F

Tantalum is essentially inert over the potential range studied. The nitride, on the other hand, shows substantial corrosion at potentials more positive than 0 mv. A small amount of oxygen activity is observed below + 100 mv. Corrosion is observed for TaC above + 630 mv, and O_2 reduction is observed below + 630 mv.

(7) <u>Cr</u>, Cr₂N, Cr₃C₂. Chromium shows little activity for O_2 reduction and corrodes to soluble chromate above + 900 mv. The behavior of Cr_2N is essentially identical. The corrosion behavior of Cr_3C_2 is apparently more complex; anodic current is observed above + 350 mv. Net O_2 reduction activity is observed below + 600 mv.

(8) Mo, Mo_2C .

Substantial corrosion current is observed for both materials. (9) W, WC, 94 WC - 6 Co, 80 WC - 20 Co.

The corrosion behavior of W and WC are essentially identical. This behavior appears to be somewhat suppressed by alloying with cobalt. Anodic current peaks are observed rather than continuous corrosion.

(10) <u>Fe, Fe₂C.</u>

 Fe_2C is somewhat more active than Fe and cathodic current is observed at more positive potentials. Both limiting currents are low (~ 0.8 - 0.9 ma/cm²), indicating incomplete reduction of O_2 . The electrical capacitances of the electrodes indicate stable surfaces on both samples.

(11) <u>Ni, Ni₃N, Ni₃C</u>.

It was difficult to prepare the carbide and nitrides as solid ingots; powder electrodes were therefore used; the preparative techniques are described elsewhere.

Ni₃N is slightly more active than nickel, and Ni₃C is two orders of magnitude more active than nickel. It is not clear whether this high activity is an inherent property of Ni₃C or due to a high surface area. Furthermore, the sample is not pure Ni₃C; nickel is also present as a major constituent.

The corrosion behavior of these compounds relative to the parent metals is given in Table XII. The data are qualitatively displayed in terms of increased or decreased corrosion.

- 34 -

TABLE XII

Relative Corrosion Behavior

| Metal | Nitride | Carbide | Corrosion Level (Metal) |
|-------|----------------|----------------|----------------------------|
| Ti | decreased | increased | low |
| Zr | small increase | small increase | none |
| Hf | no change | ? | none |
| V | decrease | decrease | high |
| Nb | no change | decreased | high |
| Та | increase | increase | none |
| Cr | no change | increase | at high potential |
| Мо | | no change | high |
| W | | no change | high |

There are no systematic trends in corrosion behavior useful in predicting the behavior of other compounds or in correlating with other pertinent parameters such as O_2 activity. The corrosion rates of VC, VN, NbC, and TiN are lower than they are for the metals. However, Cr_3C_2 , TiC, and TaC corrode faster than the parent materials. Apparently either porous or soluble products are formed since passivation currents are not observed. This effect implies that the composition of the surface oxide film normally present on the metal has been substantially altered by the presence of carbon.

The carbides are all more active than the parent metal for O_2 reduction, and some activity is found even when the metal itself is inert, e.g. Zr, Hf, Ta, and Cr. Except for the titanium compounds, the nitrides are less active than the carbides. The apparent limiting currents (at + 150 mv) for Cr_3C_2 , Fe_2C , NbC, and TaC were significantly higher than for graphite, implying that the carbides are more effective in reducing HO₂⁻.

- 35 -

The highest activities were observed for TiN, VC, Fe_2C , and Ni_3C . The relative activity of TiN may be misleading since the material had a high surface area (540 μ f/cm²). The use of VC cathodes is impractical because of corrosion at high positive potentials. Fe₂C is apparently stable over the voltage range studied so that its use is not ruled out by corrosion problems.

C. Borides and Silicides

Corrosion currents are observed for the borides and silicides of the refractory metals. Of interest are the high corrosion rates for the borides and silicides of metals which are inert in 2N KOH, e.g. Zr, Hf, and Ta. Evidently, the normally passivating film of insoluble oxide is substantially modified by the nonmetallic constituent, more so than for carbon or nitrogen.

The chromium compounds are the most stable in this group, although a small amount of corrosion current is observed for the high boron-content compounds, i.e. CrB, CrB_2 , and Cr_5B_3 . The first two of these materials also show cathodic currents. It is tempting to assign this current to reduction of soluble chromate. However, the stirring in these experiments should remove from the surface chromate produced at high potentials.

Because of these high corrosion currents, the refractory metal borides and silicides cannot be considered as possible oxygen electrodes.

The group VIII borides studied (Ni₂B, Ni₃B, Pt₂B) were relatively resistant to corrosion, although even in the case of Pt₂B anodic current was observed at high potentials. The measurement of O_2 activity indicated no enhancement due to the presence of boron.

D. Silicon Carbide

Single crystalline $6H-\alpha$ -silicon carbide most frequently grows in the direction of the c-axis, and consequently the largest surfaces will be the {0001} planes. These surfaces are monatomic, one side showing silicon atoms and the opposing parallel surface only carbon atoms.

Both surfaces, carbon and silicon, of the SiC crystal showed activity for O_2 -reduction. However, there are some differences between the two surfaces which could be related to the surface composition. The open circuit potential, though not a completely reliable parameter here, is higher on the carbon side of the crystal (700 mv vs. 500 mv). The initial cathodic current on the carbon side is observed at 525 mv vs. RHE, compared with 375 mv for the silicon side. The cathodic current at 0.0 mv is 34 μ a for the carbon side and 15 μ a for the silicon side.

These differences suggest that for SiC continuum factors are not the dominant factor in the rate of reduction of O_{2^*}

E. Ti and TiO_2

The first measurements on titanium metal vere made with a sweep from 1000 to 0 mv at 50 mv/min. O₂-reduction current was first observed at 400 mv. The diffusion limited current was not reached above zero mv. The corrosion current observed under nitrogen was of the order of $10-20 \ \mu a/cm^2$.

The reaction obviously occurs on an oxide layer down to potentials of -450 mv. When the sweep is extended to -900 mv or held at -600 mv, O_2 -reduction is apparently taking place on a clean titanium metal surface, as indicated by the large hysteresis and the exceptionally flat diffusion current plateau.

The paper of Bianchi, Mazza, and Trasatti⁽⁶⁾ asserts that in alkaline solutions of hydrogen peroxide, the "black oxide" is formed in preference to the passive oxide film. We examined the behavior of this black oxide in the potential region of O_2 reduction. The titanium electrode was exposed in the first case to 0.1 molar peroxide solution for 120 hours. This electrode was then tested for O_2 -reduction activity. The potential at which O_2 -reduction occurs is shifted to more positive values, $E_{\frac{1}{2}}$ by about 70 mv and E_1 by about 200 mv. The double layer capacity increases by a factor of approximately two.

- 37 -

In a subsequent experiment the peroxide concentration was increased to 1M. The electrode was left in solution for 20 hours and then tested for O_2 -reduction activity. It had a heavy, adherent black film on its surface. The shift in potential for O_2 -reduction was ~ 200 mv more positive; the double layer capacity increased by a factor of 25.

Current voltage curves were measured on single crystals of TiO_2 . Measurements were made on both the "a" and "c" crystals in the "asreceived" condition. The as-received crystal was slightly oxygen deficient, but from the electrochemical behavior the stoichiometry was not far removed from TiO_2 .

Interesting differences are already apparent between the two crystallographic orientations. The potential at which a reduction current is first discernible (E_i) is 100 mv greater for the c-axis crystal (at 375 mv vs. RHE) than for the a-axis crystal. The effect of the difference in conductivity can be seen in the less rapid increase of current with potential for the a-axis crystal below 275 mv.

The two samples were retested after reduction in H_2 at 1000°C for 3 hours. The temperature for this process was increased from room temperature to 1000°C in three hours. The cooling time was 15 hours; (these times were necessary to prevent thermal cracking). The resistance of this crystal (measured with a resistance meter across the electrode configuration) was about 50 ohms, which is considerably less than the original sample. The reduced sample shows an increase in activity over the original crystal. The initial cathodic current is observed in the present case at 500 mv, compared with 375 mv observed previously. The sample was subsequently swept through different potential ranges in a manner similar to the measurements made on pure titanium to check the effect of prepolarization. The results are essentially the same with one significant exception: Sweeping to -600 mv on pure titanium produces a clean metal surface and a flat diffusion current plateau on the return sweep. This was never observed on the titanium dioxide crystal.

- 38 -

Finally, a slow sweep was rerun at the end of this series, starting at the open circuit potential and going to 1000 mv before sweeping back to 0.0 mv. The initial potential at which cathodic current is seen occurs at a higher potential, ~ 750 mv, than that at which cathodic current occurs initially, ~ 350 mv.

Similar measurements were made with the c-axis crystal. Cathodic current on these crystals is first observed at 850 mv, i.e. approximately 100 mv more positive than in the a-axis crystal. Prepolarization of the electrode in anodic and cathodic directions has no discernible effect.

TANK SY THAT

IV. DISCUSSION

We can consider these callysts mainly in terms of the role of the oxide film formed on the surface during the oxygen reduction process. There are three main groups.

The first includes metals on which oxygen reduction begins only when bare metal surface becomes available - that is after substantial reduction of an oxide or chemisorbed oxygen layer. The reduction of oxygen proceeds directly to water on the bare surface with very little hydrogen peroxide accumulation. Examples of metals of this type include those of the Pt group and silver. Within this group Pt has the highest activity at low temperatures. The metals Zr, Ta, Hf, and Nb can be included in this group insofar as an oxide layer is present at all potentials and no appreciable O_2^{-1} reduction occurs.

The next group contains elements such as Ti, Ni, Fe, and graphite. Oxygen is reduced on these materials on oxide-covered surfaces with varying degrees of reversibility. For example, reduction of oxygen on passivated Ti requires an overvoltage of about 1 v, while on graphite (which is completely covered by oxygen) oxygen can be reduced to hydrogen peroxide with a high degree of reversibility.

The third group includes elements such as Mn and Co on which redox reactions of the type

 Mn^{4+}/Mn^{3+} or Co^{3+}/Co^{2+}

have specific effect on oxygen reduction. In these cases, a maximum activity is found in the range of potentials where these reactions occur. A maximum can be observed directly on pure Mn but is masked on pure cobalt by a corrosion current. It is, however, observed on Ni-Co alloys where the corrosion current is very small. The activity of the NiCo₂ alloy may be additionally due to a synergistic effect related to the spinel Co_2NiO_4 .

Gold is a special case since it is the only metal essentially free of oxide or chemisorbed oxygen below the reversible O_2^{-1} potential (1.23 v). Reduction of oxygen to hydrogen peroxide is virtually reversible on gold, while the further reduction of HO₂⁻¹ to water (or OH⁻¹) is slow.

- 40 -

In the case of the intermetallic compounds, we were principally concerned with the influence of alloy or compound formation on the intrinsic catalytic activity for the electrochemical reduction of O_2 . Again for most of these we are examining the influence of the bulk catalyst composition on the <u>surface oxide</u> formed under the test conditions, rather than the activity of the intermetallic itself.

Our experiments show that enhancement of the catalytic properties by formation of a new phase is generally small. The <u>catalytic properties</u> of the <u>components</u> of an alloy appear to be more important than the <u>electronic</u> or <u>crystallographic</u> structure of any phase that may be formed. However, compounds or alloys may show substantially higher activity and stability than do the components. This result is generally due to the effect of the electronic or crystallographic structure of the compound on the properties of the surface oxide formed during oxygen reduction on all nonnoble metals.

A substantial effect of chemical compound formation is also apparent in corrosion.

Of the specific systems studied, the intermetallic compounds of platinum and nickel and the interstitial compounds of the transition elements with carbon and nitrogen are of particular interest.

From our study of intermetallic compounds of Pt with nonnoble metals we may conclude that:

(a) Appreciable dilution by a nonnoble metal (e.g. Pt₂Ta) causes no decrease of the platinum activity for comparable surface roughness factors.

(b) Considerable surface increase can be obtained in some intermetallic compounds, probably by leaching of the nonnoble metal component. This effect may be useful in obtaining platinum particles with a high and stable surface for practical electrodes.

(c) Although addition of cobalt to nickel imparts a considerable increase in activity, $PtCo_3$ does not show a corresponding improvement. This may be due to the high intrinsic activity of Pt. This conforms to the general pattern observed, namely that no intermetallic compound tested to date shows more activity than platinum.

- 41 -

Nickel alloys with Co and Mn show improvement in performance over nickel. The corrosion resistance of a metal which corrodes in alkali is improved, on the other hand, by addition of Ni. This general trend was noticed for all nickel alloys; the best example was NiAl which behaved exactly as nickel.

 ${\rm Ti}_3{\rm Au}$ is a particularly interesting intermetallic compound. Its initial performance is higher than titanium or gold (but somewhat lower than platinum). With time, this performance increased to a level higher than platinum, but it was accompanied by a pronounced increase in double layer capacity, implying roughening of the surface. This was confirmed by electron microscopy. Analysis of the surface with an electron microprobe showed the surface exposed to the electrolyte to be more rich in titanium than was the bulk of the sample. This is discussed in more detail later.

Of the 'interstitials' of the refractory metals, borides and silicides generally exhibited high corrosion currents, which eliminated them as possible oxygen electrodes in caustic electrolytes.

The nitrides and carbides are another matter, especially in the cases of VC, VN, NbC, and TiN all of which are more resistant than their parent metals. The carbides (and the nitrides to a lesser extent) are all more active for O_2^{-1} reduction than the parent metals; some activity is found even when the metal itself is inert, for instance with Hf, Ta, and Cr.

Another example of interest is Ti and TiN. The decrease of corrosion current and of overvoltage for O_2^{-1} reduction (about 500 mv) observed with TiN is hard to explain as a pure surface area effect and must be due to the favorable effect of an oxynitride of titanium covering the TiN surface.

- 42 -

THE TAY AS TAKE & PE

The essential points to come out of the measurements on the single crystals of TiO_2 are that the reduced form (particularly the c-axis crystals) does support a cathodic current corresponding to reduction of oxygen at potentials > 500 mv and is stable (i. e. does not revert to TiO_2 stoichiometry during the time interval of the experiments in the potential range of interest (600-1200 mv). This latter point is well demonstrated by the fact that prepolarization to both cathodic and anodic potentials beyond this range has no effect on the current voltage characteristics. The anodic (and cathodic) currents noted in the potential range 300 to 1000 + mv with the fast sweep method can be attributed to the double layer charging current, both from the dependence on the direction of the sweep and the fact that the current decays rapidly when the sweep is stopped or the sweep rate reduced. The magnitude of this charging current indicates a significant roughness factor for these crystals.

The behavior of the black oxide on titanium and the nonstoichiometric TiO_2 is quite similar and even if the absolute activities are low considerable increases can be obtained by modification of stoichiometry.

Sufficient electronic conductivity exists in the oxide to sustain relatively high rates of O_2 reduction on single crystal surfaces and on thin films on the metal surface when the total amount is small. However, this conductivity is not high enough to provide the current paths for the high currents to be expected in the finely divided form in PTFE bonded electrodes. This would account for the inactivity of the finely divided Ti₃Au electrode.

SECTION 2

THE ACTIVITY OF GOLD ALLOYS OF PRECIOUS METALS AND SILVER MAGNESIUM ALLOYS (SOLID ELECTRODES)

I. GOLD ALLOYS OF SILVER, PALLADIUM, AND PLATINUM

A. Introduction

These alloys are of interest because of the gradual changes in electronic configuration and lattice parameters which can be induced by alloying. In addition, some new surface oxide characteristics may exist for these alloys. It has been found that oxide layers of Pt, Pd, and Ag do not catalyze O_2 -reduction to the same extent as the bare metal does. Consequently alloying with gold, which does not form surface oxides, may lend some noble characteristics to the alloys. It should be noted, however, that the absence of an oxide layer does not ensure catalytic activity for O_2 -reduction. Gold, for example, catalyzes the reduction of O_2 to HO_2^- quite reversibly but shows considerable irreversibility in the second step, the reduction of HO_2^- to OH^- .

One of the purposes of this work was to try to distinguish between the electronic effects and the influence of the oxide layer. Special precautions were taken (a) to keep the composition of the surface constant (i. e. avoiding selective segregation of components), (b) to control diffusion conditions and (c) to minimize the effect of impurities.

B. Experimental

The rate of oxygen reduction was measured on gold, platinum, palladium and silver and the alloys Au/Pd, Au/Pt, and Au/Ag at 10% increments of composition. The electrodes were machined and polished cylinders 0.6 cm high and 0.6 cm diameter and were mounted in a holder described by Makrides and Stern⁽²⁾. The actual geometric surface area was determined accurately in

- 44 -

each case. All tests were made in 2M potassium hydroxide (Baker Analyzed) at $25^{\circ}C \pm 0.1^{\circ}C$. Further tests on selected alloys were made at 75°C. The reference electrode was a reversible H₂ electrode separated by a Teflon frit. After preliminary tests with Pt and graphite the counter electrode was changed to a large folded piece of Pd-Ag foil precharged cathodically with hydrogen in order to maintain its potential below 100 mv vs. RHE for the duration of the test. (The reason for selecting this counter electrode is discussed later.) The solution was presaturated with nitrogen for corrosion tests and with oxygen for the activity determination. The electrode was rotated at 600 rpm.

Mass transport to an electrode of the described configuration cannot be strictly defined by a simple equation such as the Levich equation for rotating disc electrodes. Consequently, an experiment was performed to determine the transport contribution from the sides and the bottom of the electrode to the total current. The implications of this information are discussed in the next section.

Three experimental techniques were used to establish the characteristics of the alloys:

(1) Fast potential sweeps (500 mv/sec) carried out in the presence of a N_2 saturated solution to determine the nature of surface oxidation of the alloys.

(2) Slow sweeps (50 mv/min) in an O_2 saturated solution to define the current voltage relationship for the O_2 -reduction reaction.

(3) Capacity measurements to determine the relative surface roughness.

The electrode potential was controlled at all times with a potentiostat, and the signal source was either a fast or slow function generator. The E (I)-curves were followed on an X-Y recorder, or an oscilloscope in case of fast sweeps and capacity measurements.

- 45 -

Typical fast sweeps are shown in Figs.3a, 3b, and 3c. The potential range for these fast sweeps was 0 to 1600 mv vs. RHE except for the gold palladium alloys. For these alloys the potential was kept above 400 mv vs. RHE to avoid the absorption of H_2 by palladium, since the subsequent oxidation of the H_2 masks the surface oxidation processes being studied. Farticular precautions were taken to prevent surface roughening and changes of surface composition of the alloys. The samples were repolished for each experiment; in addition, the number of potential cycles applied to the electrode, before the fast sweeps were recorded, was restricted to four sweeps, the first three being used to align the trace on the oscilloscope. For the slow sweep, the electrode was again polished and the potential restricted to 600-1000 mv. The higher limit was set to avoid surface composition changes due to oxidation above 1000 mv, and the lower limit was intended to minimize the duration of the experiment and thus avoid accumulation of peroxide in the electrolyte. A typical example of a slow sweep curve is shown in Fig. 4.

The capacity of each electrode was measured in N_2 -saturated solution prior to the O_2 -reduction activity determination. The technique consisted of the application of a small triangular wave (25 mv, peak to peak) to the electrode at 600 mv vs. RHE (to conform to the potential restriction mentioned above). The resulting square wave of current was used to calculate the double layer capacity.

Effect of Impurities

Gold was chosen as the electrode material for the investigation since it allows the most sensitive measurements of side reactions.

In the initial tests, there were two unexpected features in the experimental curves. These were (1) an unusual cathodic peak in the limiting current during the return sweep (increasing potential) at 250-500 mv and (2) an anodic current, also observed with gold, at potentials > 900 mv, which varied with time and immediate past history of the system. Both of these factors were important in considering our present objectives.

- 46 -

ŕ

a. 11

L

MARTE STATES

572F

The peak in the limiting current was undesirable because it prevented precise definition of $E_{\frac{1}{2}}$ and because it was an indication of an impurity in solution that was actively involved in the oxygen reduction reaction. The anodic current was undesirable because it occurred in the potential region where the O_2 reduction process is activation controlled. The activation controlled region (Tafel region) of the current voltage curve is that where the surface reaction, which is dependent on the catalytic activity of the electrode, controls the over-all rate of the reduction reaction. Measurements of the rate, the current density per real square centimeter of the surface as a function of potential in this region, is a means of assessing the activity of the electrocatalyst. Therefore, the presence of a simultaneous anodic process of any magnitude restricts precise determination of the electrocatalytic activity toward the O_2 reduction process (further discussion below). Prior to making the experimental measurements on the three systems, the possible causes of the anodic current and the cathodic peak were investigated.

The anodic current occurred at all potentials > 800 mv under N_2 . Under O_2 the anodic current was not observed until higher potentials (~ 950 mv), but it was assumed that the anodic reaction occurred simultaneously at the lower potentials, affecting the magnitude of the observed cathodic current. The anodic current tended to increase with time and frequently showed a sharp increase after the determination of a current voltage curve under O_2 .

This behavior corresponds to the accumulation in the electrolyte of H_2O_2 (or more precisely HO_2) produced by the incomplete reduction of O_2 . This is particularly the case when the electrode material is not a good peroxide decomposition catalyst. To check the effect of peroxide accumulation, hydrogen peroxide was added to the electrolyte to make a 10^{-3} M solution. The anodic current increased by a factor of 10^3 . If it is assumed that the current is diffusion controlled, then the anodic currents usually observed correspond to a solution 10^{-6} M in peroxide. This level of concentration may occur under the normal operating conditions, particularly since the electrode is at low positive potentials for quite long periods during the slow sweep measurements. A large

- 49 -

175. W. A. T. C.
gold scavenger electrode was introduced to the system and maintained at a potential of 1000 mv vs. RHE, in order to consume accumulated peroxide. However, this electrode was apparently not as efficient as was expected in the oxidation of HO_2^- , since it did not reduce the magnitude of the anodic current, possibly because of poor transport of HO_2^- to its surface.

The anodic currents have been minimized by working with fresh electrolyte for every determination, by conducting the measurements in the shortest possibly time, and by using a restricted potential range for the slow sweep studies (see below) thereby reducing the amount of peroxide produced.

The cathodic peak in the limiting current of O_2 -reduction to HO_2 is a catalytic peak. It did not appear when the potential was maintained above 300 mv vs. RHE. Furthermore, the current peak never exceeded the theoretical limiting current to be expected from reduction of O_2 to H_2O . This suggests that the effect was possibly due to the complete reduction of O_2 to OH⁻ catalyzed by a metal deposited at the low potential. Kronenberg⁽⁷⁾ has reported a 1M solution of KOH containing 1-10 ppm of Fe, Ag, Cu and Cr. For iron, a 5 ppm impurity level corresponds to a 10⁻⁴M solution.

Another source of impurities that was considered was the counter electrode. Initially, Pt was excluded from the system because of its possible dissolution and deposition on the surface of the working electrode, which could change its character, including oxygen film formation at lowered potentials. Measurements carried out with a graphite counter electrode indicated that it contained leachable impurities. Gold was excluded on the same basis as Pt. Any gold deposited on the working electrode would not show the difference in activity expected of Pt but could give rise to a continuously changing surface composition in the case of the alloys. The system selected for the counter electrode was a large piece of Ag/Pd foil charged with H₂. The anodic process that occurs to complement the cathodic reduction of O₂ is hydrogen oxidation, and since this occurs at < 100 mv vs. RHE, no metal dissolution can occur.

- 50 -

C. Results

A typical E-log i curve is presented in Fig. 5. The linearity of the curve for over a decade of current suggests that in this particular region the reaction is activation controlled.

The activities of the complete range of alloys are presented in Figs. 6 and 7 at the potential corresponding to a particular current density in the Tafel region; the current was normalized for the real surface area of the electrodes using the double layer capacities measured previously. Also shown in Fig. 8 are the activities defined in terms of potential at a constant current density (per geometric square centimeter). The pattern of activity is the same.

The order of activity was Au/Pd > Au/Pt > Au/Ag; for the 1:1 alloys the following E_i values were recorded for $i = 50 \ \mu a/cm^2$: Au/Pd -926 mv, Au/Pt - 878 mv, Au/Ag - 856 mv vs. RHE. The Au/Pd series exhibit a flat maximum of activity over the range 70/30 - Au/Pd to 30/70 -Au/Pd; the Au/Pt and Au/Ag alloys show, with some scatter, a steady transition from the activity of one pure component to the other. The activity patterns are approximately the same at 75°C(Fig. 9). The enhanced activity of the Au/Pd alloys is not unexpected and has been reported in the literature ^(8,9). An interesting feature of these results is that at 25°C pure Pd ($E_{50} = 922 \text{ mv} \ vs.$ RHE) is more active than pure Pt ($E_{50} = 880 \text{ mv} \ vs.$ RHE). As the temperature was increased from 25°C to 75°C, the activity (E_{50}) of pure Pt increased from 880 to 903 mv, while that of Pd decreased from 922 to 915 mv. In other words, at 75°C and 50 $\mu a/cm^2$ Pd was still somewhat more positive (12 mv) than Pt.

An important reason why Pd has not been extensively used in practical fuel cells is that it is known to corrode at a significant rate at positive potentials in KOH (or in acid) at 75°C and above. The anodic current observed at 1000 mv was 3 μ a/cm² for Pd compared with 1 μ a/cm² for Pt, though no great significance should be attached to the absolute value of these figures. It is therefore of considerable interest to note that the activity of Pd is

maintained or even enhanced in the gold alloys up to 70% Au, particularly since it might be expected that the corrosion resistance of the alloys would be better than that of pure Pd, as is the case for the Ni alloys of Mn and $Co^{(4)}$.

In the fast potential sweeps separate peaks for the O_2 desorption process (cathodic current) are observed on the Au/Pd and Au/Pt alloys (Figs. 10-12), the relative magnitudes changing with the alloy composition. This indicates that for the most part, as shown in our study of intermetallic compounds, the component metals retain their individual characteristics with respect to oxide reduction and do not exhibit any composite properties. There is less differentiation of peaks, except in magnitude, among the Au/Ag alloys since the pure metals under these conditions behave in a similar manner. Another indication that the component metals retain their individual characteristics is the observed differences in limiting current density for 10% additions of Ag, Pd, or Pt. At room temperature the reduction of O_2 on gold proceeds only to peroxide at low polarization, wheras platinum, palladium, and silver are all effective peroxide decomposition catalysts. It is interesting to note that the limiting currents are doubled for only a 10% addition of these components to Au. See Table XIII.

A number of these alloys have been prepared in a finely divided form and tested as practical fuel cell electrodes (sections 3 and 4).

II. SILVER-MAGNESIUM ALLOYS

A. Introduction

We have tested silver-magnesium alloys under similar experimental conditions to those described for the gold alloys. The principal reason for this was that Beer and Sandler⁽¹⁰⁾ have examined these catalysts for the oxygen-reduction reaction, with different surface pretreatments, and have reported improved performance for a 1.7% Mg:Ag alloy. This was considered to be related to its enhanced secondary electron emission. This work did not include a determination of the real surface area of these materials. A comparison of the real surface areas of Ag and the alloy was carried out in this laboratory in conjunction with activity tests on these materials.

B. Experimental

The silver-magnesium alloy was obtained as foil from Handy and Harman Co., New York, and silver foil was purchased from Williams Metals. The foils, welded to an Ag-wire and sealed in glass, were polished to a bright finish with alumina and tested in a rotating electrode cell as 1 cm by 1 cm squares.

C. Results

The current potential curves for these materials are shown in Figs. 13 and 14. A comparative figure for the real surface areas of the Ag and Ag:Mg foils was obtained from the ratio of their double-layer capacities. The capacities were measured with a 50 mv triangular sweep at 400 and 700 mv at the beginning and at the end of each activity determination. The ratio of the real surface areas ranged from 3. 2 to 6, the Ag:Mg alloy having the higher surface area. A series of experiments at different sweep rates showed that the surface was substantially free of adsorbed impurities.

A comparison of the potentials at a current density of 200 μ a/cm² (corrected for the difference in surface roughness), where there are no mass transfer limitations, shows no greater intrinsic activity for the Ag:Mg alloy (Table XIV).

SECTION 3

PREPARATION AND TESTING OF FINELY DIVIDED CATALYSTS

I. PREPARATION OF FINELY DIVIDED CATALYSTS

The screening program described in the first two sections of this report indicated that a number of materials were potentially good catalysts for oxygen reduction. In order to verify this, it was necessary to prepare these materials in a finely divided state. In some cases, as with the gold alloys, a variety of precipitation methods were available but for other materials, such as titanium gold and nickel carbide, more complex techniques were needed. These preparative techniques are described below for Au-Pd, Au-Pt, Pt-Os, Ti₃Au, TiAu, TiN, Ni₃N, and Ni₃C.

A. <u>Gold-Palladium Alloys</u>

Previous measurements on gold alloys of Pt, Pd, and Ag showed the Au/Pd alloys to have the highest activity for O_2 reduction. Furthermore, this high activity (higher than pure Pt and pure Pd) extended over a wide range of alloy composition from 20 to 70% gold. The high activity of the gold rich alloys is particularly encouraging since these alloys are more corrosion resistant than pure Pd. Pure Pd is active for O_2 reduction but does not show the corrosion free behavior of pure Pt.

The following alloy compositions were chosen for preparation: Pd-Au 40/60, Pd-Au 50/50, Pd-Au 60/40, and Pd-Au 70/30. Three precipitation methods were used -- formaldehyde reduction, hydrazine reduction, and hydroxylamine reduction.

1. Formaldehyde Reduction

The formal dehyde reduction of a solution of H $AuCl_4$ and PdCl₂, for preparation of the black, avoids the complications of the widely used borohydride reduction, which has two disadvantages: the possible introduction of boron into the product and the difficulty of predicting the composition of the product. The formaldehyde reduction has been used extensively at Tyco for the preparation of Pt blacks in a reproducible manner. The key to reproducibility is the control of the nucleation and mixing stages of the preparation. The method is based on the work of Turkevich, Hillier and Stevenson⁽¹¹⁾ and has been described in detail elsewhere⁽¹²⁾. Briefly, precipitation occurs in strongly alkaline solution by an electrochemical mechanism on preformed nuclei in solution; formaldehyde is oxidized at one site and the metal ion is reduced at another site on any given nucleus. The formation of nuclei, a slower molecular reaction, can be induced at lower pH where the rate of the electrochemical process is negligible. By separating the nucleation step and the growth (electrochemical) process by adjusting the pH, a more uniform product can be prepared.

The experimental procedure was to take a portion (1/4) of the gold palladium solution (6. 160 g of H AuCl₄ and 6. 465 g of PdCl₂ in 475 ml of water filtered through a Millipore filter)* and add twice the stoichiometric requirement of formaldehyde followed by sufficient sodium carbonate to bring the pH to 8.5. After ten minutes, during which time (as shown for Pt) the number of nuclei has reached a constant value, this solution and the remainder of the gold palladium solution (plus formaldehyde) is added rapidly (< 2 sec) to a vigorously stirred solution of NaOH at 90°C. The precipitation of the black, including agglomeration, was complete in 3 min. Oxygen was bubbled through the system during the reaction and for ten minutes afterwards. The black was collected, washed free from sodium chloride, and allowed to dry in air.

- 63 -

^{*} All solutions were passed through a Millipore filter capable of removing particles down to 0.2μ ; this reduced the possibility of heterogeneous nucleation, a source of irreproducibility.

2. Hydrazine Reduction

In this method hydrazine was added to the Au and Pd salts dissolved in methanol: Five preparations were made, the first at 90° C and the rest at room temperature. The blacks were collected, washed free of chloride, and dried in air.

3. Hydroxylamine Reduction

Hydroxylamine hydrochloride was added dropwise to the chosen alloy composition of Au and Pd salts (Pd-Au 40/60). The reaction was carried out at room temperature, 75° C, and 85° C. The blacks were collected, washed, and dried in air.

B. <u>Au-Pt</u>

In the testing of the gold alloy series as solid electrodes, it was found that, unlike the gold palladium series, the gold platinum alloys showed little if any improvement over the performance of platinum for oxygen reduction, with the exception of the 70% Pt composition. A black was made of this composition, Pt-Au 70/30, by the formaldehyde reduction method described above.

C. Platinum

Since the formaldehyde reduction method seemed to be the most promising, a platinum black was prepared with formaldehyde as a testing reference. The technique was originated as a platinum black preparation, as described in the gold palladium section above.

D. Pt-Os

Three platinum-osmium preparations were made, two by formaldehyde reduction and the other by mechanically mixing platinum and osmium powders. The precipitated material, theoretically Pt-Os 80/20, possibly had less osmium than indicated due to its difficult reduction. X-ray analysis was inconclusive. The mechanical mixture was impractical because of the large differences in particle size of the platinum and osmium.

E. Platinum-Silver

Platinum-silver electrodes (Pt-Ag 30/70) were made by mechanically mixing Englehard Pt black with Fisher Ag₂O powder. These electrodes were made in order to study the improved performance, apparently due to structural effects, observed previously with this composition.

F. Ti₃Au

Measurements on solid rotating electrodes of Ti_3Au showed it to be intrinsically more active than Pt. Several attempts were made early in the program to take advantage of this high intrinsic activity with a practical, high surface area form of the catalyst. It was found then that a Ti_3Au powder (-325 mesh), prepared by grinding and made up as a PTFE bonded electrode, effervesced vigorously on contact with 35% KOH. The catalyst/PTFE mixture expanded 50% in volume and separated from the support screen. No activity was observed either during or after effervescence.

An electrode prepared from Ti_3Au powder that had been leached in 35% KOH at 60°C for 50 hours (at which time all effervescence had stopped) was also inactive. This powder had a large content of a voluminous white component, probably TiO_2 . A large TiO_2 content could explain the low conductivity of the leached powder and might also account for the absence of catalytic activity for O₂ reduction. Since TiO_2 is soluble in dilute acids, an acid wash (25% H₂SO₄) was introduced into the catalyst pretreatment to decrease the TiO_2 content.

In all, twenty-four preparations were made in which the KOH leaching conditions and acid washing conditions were varied.

G. <u>TiAu</u>

TiAu, when exposed to KOH, does not leach to the same extent as does Ti_3Au . In addition, it also shows high oxygen reduction activity. However, unlike Ti_3Au which is brittle, TiAu cannot be broken up by the usual pulverizing techniques. In order to obtain a powder, the vacuum

- 65 -

deposition technique was used. A small ingot of TiAu was brought to a suitable temperature in an evaporator at a helium pressure greater than one Torr. The powder which accumulated on the walls of the bell jar was collected by brushing the surface with a camel hair brush. Half of the sample was given a dilute sulfuric acid wash (which removed a large portion of the material).

H. $\underline{\text{TiN}}$

The preparation of the titanium nitride involved the evaporation of titanium metal in a N_2 atmosphere at 50 μ pressure. The titanium nitride was blue-grey in color; (stoichiometric TiN is a golden yellow). Since the N_2 pressure during evaporation controls the condensation rate and therefore the particle size, it is unlikely that the stoichiometric form of TiN can be prepared in finely divided form using this method.

I. Nickel Nitride

Only one successful preparation of nickel nitride was made. This was based on the reduction of carbonyl nickel in H_2 at 450°C for 24 hours, followed by nitriding at 300°C with NH_3 for 48 hours. X-ray measurements showed 58% Ni_3N . Five other attempts to reproduce this preparation were unsuccessful.

J. Nickel Carbide Prepared by Acetate Decomposition

Thirty-two samples of Ni_3C and two samples of Ni/Co were prepared at Tyco by thermal decomposition of nickel and cobalt acetates in N_2 , according to the method of Leicester and Redman⁽¹³⁾. The initial experiments based on this method were to a large extent responsible for the interest in the survey of interstitial compounds prepared by the Bureau of Mines.

The acetate crystals were first dehydrated by heating to 100° C on a hot plate for 1 hour. The thermal decomposition was carried out in a furnace with N₂ flowing over the sample. The times and temperatures of decomposition of the active samples are listed in Table XXVII. The inactive samples,

- 66 -

many of which were prepared under conditions apparently identical to the active catalysts, are not listed. For the Ni/Co alloy carbides the starting material was either a solution of the acetates evaporated to dryness or the crystals ground together in a pestle and mortar.

K. Bureau of Mines' Catalysts

The carbides, nitrides, carbonitrides and nitrocarbides of iron, nickel, and cobalt are an interesting group of catalysts many of which have been investigated in detail in connection with the Fischer-Tropsch reaction⁽¹⁴⁾. Because of their metallic properties and their possible enhanced resistance to oxidation as compared with their parent metals, this class of materials presented attractive possibilities as oxygen reduction electrocatalysts. Measurements with porous Ni₃C electrodes described in the previous section showed very high activity for O₂-reduction, at least for short-term measurements. In addition, initial measurements on an iron rod carbided on the surface demonstrated that iron carbide had a somewhat higher activity than pure Fe.

A range of interstitial compounds of Fe, Ni, and Co in finely divided form were prepared by the Bureau of Mines as part of a cooperative program. The preparation of these materials, as described in the Bureau of Mines' quarterly reports⁽¹⁵⁾ are reproduced below.

Marray Strates

92R 1Ag-1 Pt. An alkaline aqueous suspension of Pt-black was treated with a solution of silver nitrate at room temperature with vigorous stirring. The solid was washed, dried and reduced with hydrogen at 2500 hourly space velocity, 250°C for 89 hours.

93R 1Ag-1Pt. Silver hydroxide precipitated on Pt-black, as in 92R. Reduced with hydrogen at 2500 hourly space velocity, 250°C for 89 hours.

94R 1Pt-1Pd. A mixed solution of Pt and Pd in aqua regia was made alkaline with NaOH, and then treated with a solution of sodium formate with vigorous stirring at 90°C. The solid was washed, dried and reduced with hydrogen at 1000 hourly space velocity, 250°C for 85 hours.

95R 3Pt-1Pd. Preparative method as in 94R. Solid reduced with hydrogen at 1000 hourly space velocity, 250°C for 85 hours.

96R 3Pd-1Pt. Preparative method as in 94R. Solid reduced with hydrogen at 1000 hourly space velocity, 250°C for 85 hours.

97R 1Au-1Pd-1Ag. A mixed solution of Au and Pd in aqua regia was made alkaline with NaOH and the precipitate so obtained was washed free of chloride ions. The material was then suspended in water, made alkaline, and treated with a solution of silver nitrate with vigorous stirring. The solid was washed, dried, and reduced with hydrogen at 1000 hourly space velocity, 250°C for 85 hours.

98R 1Ni-1Pt-1Pd. A mixed solution of Pt, Pd, and Ni was made alkaline with NaOH and then treated with sodium formate, with vigorous stirring at about 90°C. The dried powder was reduced with hydrogen at 2000 hourly space velocity, 250°C for 85 hours.

99R 1Ag-1Au-1Pt. Gold as hydroxide and platinum as Pt-black were prepared separately and washed free of chloride ions. They were then mixed together and suspended in water. The suspension was made alkaline and treated with a solution of silver nitrate, with vigorous stirring at room temperature. The washed and dried solid was reduced with hydrogen at 2000 hourly space velocity, 250°C for 85 hours.

- 83 -

100R 1Ag-1Pd-1Pt. A mixed solution of Pt and Pd in aqua regia was made alkaline with NaOH and then treated with a solution of sodium formate with vigorous stirring at 90°C. The solid was washed free of chloride ion, suspended in water, made alkaline with NaOH and treated with a solution of silver nitrate with vigorous stirring. The threecomponent precipitate was washed, dried, and reduced with hydrogen at 1000 hourly space velocity at 250°C for 85 hours.

101R 3Ag-1Au. Washed and dried, separately prepared hydroxides of silver and gold were mixed mechanically, and the mixture reduced with hydr. gen at 1500 hourly space velocity, 250°C for 89 hours.

102R 3Au-1Pt. Pt-black and gold hydroxide were precipitated separately. Calculated amounts of the washed and dried powders were mixed mechanically, and the mixture reduced with hydrogen at 1500 hourly space velocity, 250°C for 80 hours.

103R 1Au-3Pt. Prepared as 102R. Reduced with hydrogen at 3000 hourly space velocity, 250°C for 92 hours.

104R 1Au-1Pt. Prepared as 102R. Reduced with hydrogen at 1500 hourly space velocity, 250°C for 82 hours.

105R 1Ag-3Au. Prepared as 101R. Reduced with hydrogen at 1000 hourly space velocity, 250°C for 89 hours.

106R 1Ag-1Au. Prepared as 101R. Reduced with hydrogen at 1000 hourly space velocity, 250°C for 90 hours.

107R 1Au-1Pt-1Pd. A mixed solution of Pt and Pd in aqua regia was made alkaline with NaOH and then treated with a solution of sodium formate at 90°C with vigorous stirring. The washed and dried powder was mixed mechanically with a separately prepared powder of gold hydroxide and the mixture reduced with hydrogen at 1000 hourly space velocity, 250°C for 86 hours.

II. ELECTROCHEMICAL TESTING OF FINELY DIVIDED CATALYSTS

The testing of highly dispersed catalysts presents many problems that are not experienced with the testing of solid electrodes. These are discussed in detail before the presentation of the data, because the interpretation of the data depends to a great extent on an appreciation of these problems.

The high area surface of a catalyst is not used to its full advantage unless the electrode structure into which it is incorporated offers good mass transport characteristics to all regions of the surface. The plastic (PTFE) bonded **electrode**⁽¹⁶⁾ undoubtedly comes closest to realizing this objective for a practical catalyst.

In these electrodes the catalyst is mixed with a dispersion of PTFE and spread on a nickel screen. The effectiveness of this structure depends on (a) the hydrophobic nature of the binder to provide gas contact to the interior surfaces of the electrode and (b) the porosity of the catalyst (the pores fill with electrolyte by capillary action) to provide electrolyte contact at all the reaction sites of the surface. Thus a catalyst of good intrinsic activity, in a highly dispersed form, must also have a pore structure conducive to the mass transport requirements of normal operation.

In more detail, most of the spaces between the agglomerates are wetprocled by the PTFE dispersion and provide good gas transport; some remain hydrophillic (depending on the % PTFE in the catalyst mix) and permit electrolyte penetration in depth into the electrode. However, contact between the electrolyte and a large percentage of the catalyst surface depends on a network of fine pores (pore diameter < ~ 500 Å) in the catalyst. These do not become wetproofed because the particle size of the PTFE dispersion ($\sim 0.1 \mu$) is larger than the pore diameter.

Even with a catalyst of good activity and ideal structure, the performance of a PTFE bonded electrode can vary with its method of preparation. The main variables are the percentage of plastic binder, the sintering time, and the sintering temperature. The distribution of the catalyst binder mixture on the supporting metal screen can also be carried out in several
ways. Before catalysts were tested, a familiarization program was carried out with platinum and carbon to explore these variables. Brief details are presented below.

A. Effect of Manufacturing Techniques on Performance of Porous Electrodes

1. <u>Platinum Electrodes</u>

Platinum electrodes were prepared by spraying, brushing, spreading, and rolling methods. All preparations to date have been made with approximately 30% Teflon, considered from previous work to be optimum, and a Pt loading of about 10 mg/cm². Deviations from the 10 mg/cm² loading are due to uncertainties in the expected loss of material for each fabrication method. All electrodes are cut from larger pieces to 1 cm² for testing.

2. Catalyst Distribution Methods

a. Spraying Technique

Electrodes numbered 1, 2a, TR-1, TR-2, TR-3A, TR-3B, TR-4A, TR-4B, TR-6, TR-7, and TR-8 were sprayed with an air gun to determine the relation between loading and spraying techniques. Electrodes ! and 2a were prepared on 100 cm^2 of screen, and 50% excess platinum was used for a projected 10 mg/cm^2 loading after losses. These electrodes were sintered at 260°C and had 10 $\mathrm{mg/cm}^2$ Pt. Electrodes TR-1, TR-2, TR-3 and TR-4 were prepared on 36 cm² of screen, and 20% excess platinum was used for a projected 10 mg/cm^2 . These electrodes had approximately $3-7 \text{ mg/cm}^2$ of platinum. Electrodes TR-3A and TR-4A were sintered at 260°C and showed extremely low performance; subsequently, electrodes TR-3B and TR-4B, sintered at 310°C, showed improved performance. Electrodes TR-6, TR-7 and TR-8 were also sprayed on 36 cm^2 screens with 20% excess platinum but with the following changes in technique: Cab-o-SiL was added to the platinum-Teflon mix on a 1:1 volume ratio. Since this extended the liquid volume and produced a thicker spraying mix, continuous drying was employed. These electrodes had a good uniform physical appearance and loadings $(8-10 \text{ mg/cm}^2)$ were

closer to the projected loading. However, the Cab-o-SiL may have had an adverse effect on the wetting characteristics of the electrodes. The electrodes were sintered at 285°C, since 260°C seems to be on the borderline of the critical minimum sintering temperature. The influence of sintering temperature is considered in more detail below.

b. Spreading Technique

It has been found that spraying produces the most uniform distribution of catalyst but does not work well with a small quantity of material. The spreading process (spreading a thick paste with a spatula) lends itself better to small quantities but usually does not yield uniform electrodes. Electrode TR-5 was made in this manner on 8 cm² of screen starting with no excess material; 13% of the material was lost.

c. Brushing Technique

Electrode TR-9 was made by applying a paste with a small brush to 12 cm^2 of screen mounted on a portable jig for weighing "in situ." An excess of 100% was used in order to work with a paste of the same consistency throughout application. The performance of the electrode was exceptionally high, surpassing all previous runs. This method, however, has proved to be of limited application, being restricted to very finely divided catalysts.

d. Rolling Technique

Electrode TR-10 was made by forming the platinum-Teflon into a rubbery dough and rolling it between Teflon sheets over the defined area of screen. This electrode was not made specifically for this program and consequently did not have a 10 mg/cm^2 loading. It has been found that the rolling method produces uniform electrodes with no loss of material, but they show comparatively low performance. No duplication of runs has been made.

The results are summarized in Fig. 15. The variation in performance was assumed to be mainly related to sintering temperature. This was examined as described below.

n i

ţ

B. Effect of Sintering Temperatures

A number of electrodes cut from a single sheet of electrode material prepared by the spray method were sintered at 250° C, 275° C, 300° C, and 325° C for five-minute and fifteen-minute intervals. The sintering temperatures in these experiments were accurately defined. In previous work the thermocouple controlling the sintering furnace was influenced by radiant heat. Since the electrodes were effectively shielded from the radiant heat by aluminum foil, the true sintering temperature was some 26° lower than that registered on the controller/indicator.

The two electrodes sintered at 250° C were not hydrophobic and were not tested. On the basis of these results summarized in Table XVI the sintering technique was improved and made more reliable and the optimum sintering conditions (for platinum) defined as 275° C for 15 minutes. Results obtained under these conditions compare favorably with the best previously reported for electrodes prepared in the same way. The change in real surface area during this sintering process at 275° C was measured by a BET technique. The figures before and after sintering were 22. 6 m²/g and 15. 6 m²/g respectively; the platinum black from which the electrodes were prepared had a surface area of 29.0 m²/g.

C. Carbon and Graphi - Electrodes

The performance of carbon and graphite powders were initially of interest as a basis for comparison of metal carbides. They also present a good opportunity for studying techniques of preparing high surface area electrodes, because of the wide range of samples available with such different physical properties as bulk density and surface area. They were consequently used to examine the influence of PTFE/catalyst ratio on performance. The bulk densities of the catalysts were measured to discover if a better correlation could be made in terms of a volume rather than a weight ratio. The following samples were examined; graphite with 22.5%, 25%, 27.5%, 30%, 35%, 40% PTFE content and acetylene black with 45%, 50%, 60%, 70% PTFE content. A summary of performance is given in

| | | | | |

Table XVII. The optimum PTFE contents were deduced to be 27.5% for graphite and 50% for acetylene black, although the curves showed fairly flat maxima so that these figures are not too critical.

The bulk densities were measured after vibration and after centrifuging. Each method is reproducible to about 5%, but as can be seen from Table XVIII, the agreement between the two methods is not good. This is not an unusual occurrence in the determination of bulk densities, since the particle shape factor has a different effect in the various methods of measurement (17). The data available to correlate bulk density and PTFE content are shown in Fig. 16. It is apparent that the correlation is a useful guide and that the centrifuging method gives the more consistent data.

D. Electrode Preparation

Electrode fabrication consisted of the mixing of the catalyst (after induction or exposure, see below) with a dispersion of PTFE (DuPont, Teflon 30) in a known weight ratio. This mixture was pasted on a nickel screen (100 mesh) to produce an electrode of ~ 6 cm² area. The electrodes were dried in a vacuum oven at 100°C and subsequently sintered in a stream of N₂ at 275°C. Several test electrodes of 1 cm² area could be cut from the sintered structure.

E. Electrochemical Testing

The fabricated electrodes were tested in a floating electrode cell configuration (Fig. 17) in 35% KOH at 75°C using as reference a dynamic hydrogen electrode. Current-voltage curves were determined under potentiostatic conditions using the following procedures. The electrode made contact with the electrolyte at a controlled potential of 1000 mv; the potential was almost immediately reduced to 850 mv and the current noted. The current was measured again after five minutes, the potential was adjusted to 750 mv, and the current measured as before. The current voltage curve was then determined at 50 mv intervals, each held for 5 min in the sequence $750 \text{ mv} \rightarrow 400 \text{ mv} \rightarrow 850 \text{ mv}$. For the cobalt and nickel-cobalt alloys the procedure was modified to include an anodic induction at 1600 mv for 10 min. The anodic pretreatment induction should produce complete oxidation of the surface and effectively reduce the corrosion rate during oxygen reduction, particularly with the cobalt catalysts. In the case of the nickel-cobalt alloys, the high pretreatment potentials (which may be imagined as being equivalent to heating in an oxidizing atmosphere) could contribute to the formation of a surface spinel (NiCo $_2O_4$), reported⁽¹⁸⁾ to exhibit good conductivity and catalytic activity for oxygen reduction. The complete E (i) curve 850 mv \rightarrow 400 mv \rightarrow 850 mv was measured as before.

Further modifications to the technique were introduced when experiments described in detail below showed that the activity of these electrodes

Fig. 17 Floating electrode cell.

No. of Concession, Name

- 94 -

A MARY STATE A PARTY

varied with time in an unusual manner (see Fig. 18). The current at constant potential initially increased, then remained constant for a period of time before decaying to a constant value somewhat below the initial current.

In order to compare the catalytic activity of individual samples, it was obvious that the measurements had to be made at identical points on this time curve. Since this behavior must be related to the surface oxide, two factors probably need to be taken into account: the total time the catalyst was exposed to air before testing (whether inducted or directly exposed) and the total time of exposure to electrolyte during tests.

After the initial examples the first factor was easily eliminated by preparing each electrode individually and testing as soon as possible (usually within 24 hours). Total contact time with the electrolyte was more difficult. If the fabricated electrodes were fully reproducible, complete information could have been obtained by measuring first a decay curve on one electrode and then the E (i) characteristic on another. Since good reproducibility cannot be guaranteed with PTFE bonded electrodes, the approach adopted was to make several successive determinations of the E (i) curve sufficiently rapidly to display the pattern of the activity change with time. This necessitated the use of a slow potential sweep method. After preanodization the electrode was subjected to a 100 mv/min potential sweep between 1000 mv and 400 mv. A complete curve of increasing and decreasing potential could then be obtained in about ten minutes. The sweeps were continued until the pattern of increase and decrease in current at a particular potential was observed; the tabulated values (see below) represent the highest observed activity. A careful comparison was made of the manual and sweep methods to ensure that the E (i) curves were equivalent.

F. Material Handling

The Bureau of Mines materials were delivered in sealed containers under an atmosphere of CO_2 ; the first process was to divide the sample into eight approximately equal lots. The subdivision was carried out in a glove box in a

- 95 -

572F

nitrogen atmosphere; the individual samples were contained in plastic snap top bottles that were further sealed in paraffin wax as the bottles were brought out of the inert atmosphere. A freshly prepared sample of Raney nickel was subjected to exactly the same procedures as the Bureau of Mines' materials up to the stage of wax sealing. The Raney nickel was then exposed to air and on each occasion the sample was pyrophoric, indicating the effectiveness of the glove box in each case. (The surface of Raney nickel is easily passivated by exposure to very small amounts of O_2 and becomes nonpyrophoric.)

Also, during the subdivision of the samples, the resistance of the powder was measured. The sample was contained between two pieces of Pt foil by an O ring 1/2" O. D. and 5/16" I. D. The sample was then compressed at constant pressure in a jig using a torque wrench (Sturtevant Model F-21-1 at 15 inch pounds) and the resistance measured. The resistance of exposed and inducted samples was measured in an attempt to measure the need for, or the effectiveness of, the induction procedure. The method was only used to determine major changes in conductivity (see below).

G. Induction Methods

In a finely divided state (BET surface areas in the range $10-27 \text{ m}^2/\text{g}$) many of these materials were pyrophoric. Pyrophoric oxidation probably results in the complete oxidation of the sample and, for finely divided materials, the loss of a large proportion of their surface area. Special techniques were developed to induct the materials prior to exposure to oxygen during electrochemical testing. The basis of these techniques was to carry out the initial oxidation process as slowly as possible. Thus it was hoped to limit the extent of oxidation and any significant increase in temperature to avoid appreciable loss of surface area by sintering. Some loss of surface area of the catalyst could also be expected from the heat treatment of the electrode to sinter the PTFE. This factor was examined simultaneously with the development of the induction procedure. The

- 97 -

induction procedure was based on the fact that the rate and extent of the initial oxidation of the surface was thought to be dependent on how and at what stage of the electrode fabrication process the catalyst was first exposed to air.

The experiments carried out are detailed in Table XIX. The effect of exposure to air when covered with methanol or water is believed to produce slow oxidation of the surface, either by reaction with dissolved O_2 or by progressive exposure to air during evaporation of the liquid layer. Elvax (a duffont polyvinyl resin) was substituted for PTFE as a plastic binder in the tests to investigate the effect of sintering. Elvax electrodes were prepared by dissolving the appropriate quantity of the resin in trichloroethylene at 70-80°C; after cooling to 35°C, the catalyst was added and the mix distributed on a nickel screen. The electrodes required no sintering and were tested after evaporation of the residual solvent. The results obtained with Elvax bonded Pt electrodes were equivalent to some of the better results obtained with PTFE bonded Pt electrodes, indicating that this was an effective method of catalyst testing. The life of the Pt electrode was, however, limited to about two hours, probably due to oxidation of the Elvax under the test conditions (35% KOH at 75°C). The life of Elvax-bonded electrodes prepared from the interstitial compounds was somewhat longer (3-4 hours). Other plastic binders are being examined in order to obtain longer lived electrodes.

The main conclusion drawn from these experiments was that careful induction of the catalyst produces a more active electrode and also that resistance measurements as described earlier on the dry powder are not sensitive enough to relate to activity.

The electrodes made with PTFE, in which the catalyst was exposed to air in the first case (#3, Table XIX) after sintering and in the second case (#4, Table XIX) before sintering, showed no significant difference. Both were comparable to electrode #1 (i) made with Elvax. However, this

cannot be regarded as a conclusive indication that the sintering process is not detrimental, since the test was not conducted with the catalyst in its most active form.

The induction method was further refined by the use of the following techniques:

(1) Slow oxidation in the gas phase

(2) Extension of the liquid phase induction in methanol to a sequence of organic solvents (petroleum, ether, diethyl ether, acetone and methanol), a sequence in which the reactivity and solubility of oxygen increases.

The slow gas phase oxidation was carried out by the Bureau of Mines with a second sample of material 11C. Three samples of 11C were supplied: an untreated sample, one that had been oxidized in 0. 1% O_2 in N_2 for 100 hours at room temperature, and another in 1% O_2 in N_2 for 100 hours at room temperature. All were tested as Elvax bonded electrodes and compared with further samples that had been subjected to the liquid phase induction described above. The details of the tests and the results are presented in Table XX. The uniformity of the results (all except one produced close to 20 ma/cm^2 at 600 mv) indicates that all attempts, both at Tyco and at the Bureau of Mines, to induct this material were of no consequence. This is in direct contrast to the results reported previously. Further, the activity of the uninducted sample A is higher than previously observed, suggesting that the surface was in some way conditioned prior to the induction processes. The improved efficiency of the extended liquid phase induction process was demonstrated by the induction of the original sample of 11C to produce an activity of 40 ma/cm² at 500 mv; this compares to 33 ma/cm² observed with simple methanol induction.

The induction method for the protection of the activity of Raney nickel described in German Patent 1, 185, 589 (Doehren and Jung to Varta Petrix-Union G. m. b. H.), in which the catalyst was immersed in a polyhydric alcohol such as ethylene glycol, was not successful for induction of catalyst 1JC.

III. TEST RESULTS

A. <u>Au-Pd Alloys</u>

It can be seen from Tables XXI, XXII, and XXIII that there is a wide variation in the activity of the blacks depending on the preparation, the percent of Teflon, the loading, etc., as described in the previous section on testing methods. The preparations made by hydrazine reduction (Table XXII) show the least activity — at 950 mv, < 1 ma/mg and < 35 ma/cm². The blacks prepared by hydroxylamine reduction are generally better — at 950 mv, > 1, < 2 ma/mg and < 70 ma/cm² (Table XXIII). The blacks prepared by formaldehyde reduction are generally the best, in spite of the erratic results of some electrodes — averaging, at 950 mv, higher than 2 ma/mg and less than 5 ma/mg (70-100 ma/cm²), Table XXI.

The first results with the formaldehyde preparation indicated that, in contrast to the measurements of intrinsic activity, the 70% Pd alloy (F4) was in general more active than the 30% Pd alloy (F5 and F6). The 70% alloy showed a maximum activity of 5. 23 ma/mg at 950 mv (corresponding to 68 ma/cm²), with typical results of the order of 3 ma/mg. The 30% Pd alloy gave typical results that were below 1 ma/mg at 950 mv vs. RHE; however, two electrodes — F6 vi(a) and vi(b) — prepared by the rolling technique (as opposed to the spreading technique used for the other electrodes) produced values of 3. 9 and 4. 1 ma/mg (67 and 87 ma/cm² respectively). This difference illustrates the difficulty associated with the testing of practical catalysts. Optimum performance from a particular catalyst demands several experiments to define the best method of electrode fabrication, the PTFE content, and possibly the sintering condition.

In sample F7 the palladium content was increased to 40%; since it was possible that in samples F5 and F6 the actual palladium content in the precipitated black was below 30%, the 40% Pd preparations permit some margin of error. (The original solutions contain the stoichiometric ratio of gold and palladium salts for a particular alloy. X-ray analysis of the early preparations showed the alloy black to have the desired composition; however, this was not tested for every preparation.) The activity level of 3.0 ma/mg is comparable to that of the 70% Pd alloy.

PARTY AYA CON

* ** ** C. **

In preparation F8, a portion of the reactants was brought slowly to a ph of 8.5 in an attempt to induce nuclei formation prior to the growth stage in NaOH. This was omitted in preparation F9. There is a marked difference in activity of the two catalysts, indicating that these initial factors do influence activity. The preparation without the deliberate nucleation step was the more active.

Subsequent preparations were made by simply adding dropwise the metal salts mixed with formaldehyde into the hot stirred sodium hydroxide. Preparations F15, F16 and F17 represent variations in alloy composition. F17 (Pd-Au 70/30), like F4, shows a very high specific activity, 4.7 ma/mg. F15 and F16 are better than the average of previous preparations.

B. Pt-Au, Pt, Pt-Os, Pt-Ag (Table XXIV)

The Pt-Au alloy (70-30) exhibited very good activity, 4 ma/mg at 950 mv. No other preparations, perhaps unfortunately, were attempted with this alloy system.

Pt-73-70, prepared as a testing reference for the formaldehyde preparation method, had a specific activity of 4.6 ma/mg. Many of the Pd-Au preparation discussed above, such as F-4, F-6, F-12, F-17 and the Pt-Au, compare quite favorably with this result. In addition, all of the above mentioned compare quite well with the results obtained with Englehard Pt (3.8-5.5 ma/mg).

The Pt-Os electrodes did not perform as well as expected, < 2 ma/mg; however, as mentioned under the preparation section, the percentage of osmium may have been considerably lower than indicated.

The Pt-Ag 30/70 electrodes showed widely different activity, . 3 ma/mg-4.5 ma/mg. It is apparent that structure had a very significant effect on the performance of this catalyst composition.

C. Ti₃Au

In the initial experiments, #1 and #2 of Table XXV, the powder prepared by leaching in the earlier work was subjected to the acid wash. As indicated, there was no improvement in activity.

Marrie Arritan Cal.

However, when this procedure was applied to a freshly prepared sample (#4), the activity was 32 ma/cm^2 at 950 mv vs. RHE. The complete current voltage curve is shown in Fig. 19. Three further attempts to prepare an active catalyst by acid washing were made (#5, #6, and #7); in these, the activity was lower but still significant. It was considered that the time interval between the KOH leaching and acid wash might be important. Further experiments were carried out with another batch of KOH leached powder (#9). The results of these tests — #10, #11, and #12 — are given in Table XXV; we did not succeed in reproducing the results of the earlier preparation. Sample #8, which was etched in HF, showed a low level of activity.

The remaining preparations of titanium gold consisted of variations in KOH-leaching time and acid washing conditions. The use of separate ingots as starting materials was also investigated. Two preparations #19 and #23, showed some activity. Weight loss calculations indicated that the leached product was very nearly pure gold; its structure, however, did not resemble the pure gold powder obtained by any precipitation methods tried, and it was more active than such precipitated preparations. This may have been due to the presence of residual titanium which prevented sintering and reduced malleability, yielding an electrode with a greater available surface.

D. TiAu and TiN

None of the samples of TiAu or TiN prepared by vacuum deposition showed significant activity for oxygen reduction. Free titanium may have been available in all samples, and this has been shown to be detrimental (Table XXVI).

E. Ni₃N

The activity of the Ni₃N + Ni catalyst as a PTFE bonded electrode was quite low (16 ma/cm² at 600 mv vs. RHE).

F. <u>Nickel Carbide</u>

The best result obtained with Ni₃C catalysts was an activity of 100 ma/cm^2 at 750 mv vs. RHE, with a limiting current > 300 ma/cm². Figures 20, 21, and 22 show the current voltage curves of the most active catalysts. Other results are presented in summary form in Table XXVII. For the nickel cobalt catalysts (Ni₃C + Co₂C), activities of 45 and 105 ma/cm² were measured at 750 mv vs. RHE. The latter electroile showed a limiting current greater than 350 ma/cm². Ten samples of Ni₃C and two samples of Ni/Co carbide showed very low activity (i_L < 50 ma/cm²).

The observed activities of these catalysts were very encouraging. However, the irreproducibility of the performance of electrodes and catalysts prepared in an apparently identical manner is difficult to explain. Where variations do exist in terms of the preparation of the catalysts' method of induction or electrode fabrication, no logical pattern was observed. It is possible that in the preparation of the catalyst the position of the sample in the furnace or the gas flow rate was critical. These factors were not rigidly controlled.

The discrepancy between the best results obtained with these catalysts and nickel and nickel cobalt carbides prepared by the Bureau of Mines is of greater significance and can probably be related to physical differences between the catalysts. The main difference was probably that of pore structure, which is of considerable importance in the efficient operation of the PTFE bonded electrode.

G. Bureau of Mines Materials

A complete listing of the activity of the interstitial compounds is presented in Table XXVIII. The electrodes are described by identification numbers — the first number and letter, e.g. 2C, corresponds to the Bureau of Mines' identification number of the catalyst. The italic number in parenthesis describes the electrode preparation, i.e. 2C (ii), and the final letter identifies the test (e.g. 2C (ii)a and 2C (ii)b are tests carred out on

)
separate samples cut from electrode 2C (ii). The tables also record the induction of the catalyst, and the nature and amount of the plastic binder used. The activity is presented as the current density at selected potentials. The less active materials (mainly Fe interstitials) are compared at 600 mv; most others are compared at 750 mv, with additional figures at 900 mv for those catalysts containing Ag, Au, or Pd. When two figures are quoted, these are the current densities for increasing and decreasing potentials respectively. These can differ due to differences induced in the oxide films at the lower potentials (minimum potential for these tests was 400 mv). In the case of Ni interstitials, it was noted that the pattern of activity was an initial increase, followed by a plateau of steady current and steady decay. To insure that peak activity was recorded in these cases the repetitive potential sweep method described earlier was used. The results obtained by this method are identified in Table XXVIII.

The results obtained for the <u>interstitial compounds of iron</u> were disappointingly low. The highest activities were 53 and 58 ma/cm² at 600 mv <u>vs</u>. RHE for samples 5N and 6N.

After the initial low results with the carbides, the testing method was examined closely to eliminate all possible steps in the process that could be detrimental. These were the oxidation of the catalyst surface and the possible sintering of the catalyst at the "curing" temperature of PTFE bonded electrodes. The experimental approach to these problems was described in the previous section, together with an assessment of their effectiveness. For the testing of the nitrides, carbonitrides, and nitrocarbides, all the electrodes were prepared by the preferred method using an inducted catalyst with Elvax as a binder. In addition, several uninducted samples were tested and occasional electrodes were prepared with PTFE. The results were uniformly bad with only one electrode showing a current density > 10 ma/cm^2 . This electrode 2 NC (ii)a showed an activity of 68 ma/cm^2 on first test, but this figure was not reproduced in a subsequent test. Though this activity represents the best observed for this class of materials, it does not approach the activity required of a practical catalyst. The general picture of activity for these materials, though not clearly defined, is nitrides > carbonitrides > carbides > nitrocarbides. Except where noted

in Table XXVIII, these materials did not show significant currents under N_2 . Prolonged exposure to air (after induction) for several days was found to have an adverse effect on performance.

Poor physical structure of the catalyst, particularly in the form of pore size distribution, could contribute to the low activity shown by these electrodes, but it is unlikely that a substantial increase in current density could be expected even if this were improved. The results are considered to be a reliable guide to the activity of the <u>iron interstitials</u>, and it must be concluded that these materials do not meet the requirements for a practical catalyst of the reduction of oxygen in a basic electrodes.

Three catalysts prepared by the coprecipitation of $Fe(OH)_3$ and Ag_2O showed relatively high activity, particularly for the two high Ag content materials (92 and 59 ma/cm²). This is most probably related to the silver content. The nitride and carbonitride forms of these catalysts showed lower activity ~ 20 ma/cm² and 11 ma/cm² respectively, probably due to the adverse effect of the heat treatment associated with the nitriding and carbiding processes.

The <u>carbides of nickel</u>, and nickel cobalt alloys were in general, more active than were the iron compounds. The best activity of a series of tests with Ni_3C (19C(v)) was 94 ma/cm² at 600 mv. This does not compare with the activity obtained with catalysts prepared by decomposition of nickel acetate which give currents in excess of 300 ma/cm² at 600 mv (as discussed below). Cobalt carbide (20C) showed lower activity coupled with substantial corrosion (electrolyte became blue), preanodization at 1600 mv for 10 mins reduced the extent of corrosion but did not result in improved activity.

The carbided nickel cobalt Raney alloys (25C, 26C, 27C) showed activities in the range 20 to 70 ma/cm² at 600 mv, the order of activity being 3 Ni/Co > Ni/Co > 3 Ni/Co. All these materials were preanodized at 1600 mv. Conditions that could give rise to the formation of the nickel cobalt spinel at the surface improved conductivity and enhanced catalytic activity, as has been reported for the spinel. The <u>nitrocarbides of nickel and cobalt</u> 11 NC, 13 NC, 15 NC, 16 NC showed activity of the same order of magnitude as that of the carbides, though in the case of the nickel cobalt alloys the

States of the second

observed order of activity was Ni/Co > 3 Ni/Co > Ni/3 Co. It should also be noted for the uncarbided <u>Raney nickel cobalt alloys</u> (RAL 1, 2 and 3) the activity was in the same range, the Ni/3 Co alloy giving 60 ma/cm² at 600 mv. For the Raney alloys the activity pattern was Ni/3 Co > Ni/Co = Ni/3 Co.

In view of the demonstrated capabilities of Ni₃C catalysts prepared from the acetate, the much lower activity of the alloys prepared from the Raney alloys was unexpected. X-ray characterization showed the catalysts from both sources to be very similar. The acetate material had a higher free nickel content; the Raney material was obviously composed of smaller crystallites as evidenced by the line broadening of the X-ray pattern. The difference in activity can most probably be attributed to differences in the physical structure of the catalysts prepared by the two methods. A second sample of Ni_3C (36C) was prepared from the Raney alloy pulverized to < 250 mesh, to check whether gross particle size could affect electrode performance. The results, a maximum activity of 30 ma/cm 2 at 600 mv, were not encouraging. Sample 50C represented an attempt to carbide a Ni/Co alloy obtained by decomposition of nickel formate and cobalt acetate. The activity was still very low (33 ma/cm²), but a second sample carbided at a lower temperature showed considerable improvement at 125 ma/cm² at 600 mv.

Several catalysts were prepared in which gold, silver and palladium were added to the Ni and Co. The performance of these catalysts themselves and as carbides was, in some cases (e.g. 44C), very good. Probably this is due to the activity of the precious metal itself, though the presence of the precious metal could improve the utilization of the nonnoble metal component by providing a lower resistance current path in the electrode structure. In these cases the structure of the Raney alloy catalyst was capable of supporting limiting currents of 350 ma/cm² (44C (ii) but this could easily be adversely affected by the carbiding process. Carbided porous nickel plaques were used for three tests on Ni₃C (28C). This electrode configuration gives a high surface area catalyst without the possibility of the high resistance that could occur with the particle-to-particle contact of the highly dispersed catalyst. The difficulty in testing

CARTAN AND THE CAR . .

these electrodes was to establish the gas electrolyte interface throughout the electrode structure. In the results reported, this was attempted by partial wetproofing, with PTFE dispersion, so that the electrodes could be run in the floating electrode cell. The recorded performance shows that the attempt to produce an extended interface was not very successful. The material was tested in a conventional fuel cell configuration with a matrix electrolyte (see section 4). Under these conditions the pressure differential between the electrode and the electrolyte was varied to obtain optimum performance.

The unusual decay pattern associated with the activity measurements on nickel and nickel cobalt catalysts was described above. A tentative explanation for this can be given as follows:

Initially, in addition to the cathodic reduction of O_2 , there is a simultaneous anodic process associated with further oxidation of the surface. This falls rapidly to a low value when the surface is completely covered and produces an apparent increase in the net cathodic current. The oxygen reduction process is assumed to occur on the oxide surface and not on the bare metal. (However, it is surprising that the surface oxidation is not complete during pretreatment of these electrodes at 1600 my for 10 minutes.) The decay process that was then observed may be related to an increase in the resistance of the electrode. The operation of PTFE bonded electrodes depends on good electrical conductivity between individual catalyst particles, and since conductivity of the oxide is considerably lower than that of the metal, the electrode resistance increases. The points or faces of contact probably oxidize more slowly than the exposed surfaces, so that this process would not be complete within the time span of the surface oxidation responsible for the apparent increase in current described above.

The above argument suggests that some of the iR corrections made to the earlier results might be too large. The ohmic resistance was measured by the interrupter technique (resolution time 0.2 μ sec). The over-all resistance measured for the nickel and nickel cobalt electrodes is approximately twice that measured with a Pt electrode, indicating a

AL MENTER MAN

significant contribution from the resistance of the electrode. This resistance, in contrast to the bulk electrolyte resistance, is inevitable in the practical operation of the electrode and may not be a valid experimental correction of the E(i) curve. The over-correction, about 0.60 or 60 mv at 100 ma/cm², is important only for those electrodes with high activity. In the results presented in Table XXVIII, this factor has been taken into account.

Sample 39 NC, nickel nitrocarbide, represents one of the best nickel catalysts tested. An unusual feature of this result (70 ma/cm² at 750 mv vs. RHE) is that it is higher than that recorded for the carbide from which it was prepared (49 ma/cm^2 at 750 mv vs. RHE). In most cases either the values for the corresponding carbide and nitrocarbide are of the same order of magnitude or the nitrocarbide shows a lower result, e.g. 41 NC = (32 ma/cm^2) and 56C (35 ma/cm²), and 42 NC (130 ma/cm²) and 57 C (137 ma/cm²). Samples 57C and 42 NC, nickel/palladium carbide and nitrocarbide respectively, show the highest activity yet observed for an interstitial compound, disregarding the 350 ma/cm² observed for nickel silver gold carbide in which most of the activity can probably be attributed to the silver and gold. A comparison of 57C with 55C (34 ma/cm²), a nickel palladium carbide prepared from the Raney alloy, emphasizes the better physical characteristics that are obtained when the carbide is prepared from the reduced coprecipitated hydroxides. (In contrast the Ni Ag Au carbide prepared by coprecipitation showed little activity, whereas the Raney alloy derivative was very active, see above).

The nickel cobalt nitrocarbide (45 NC) and carbide (61C) prepared from the reduced coprecipitated hydroxides, however, showed negligible activity (< 1 ma/cm^2 at 750 mv vs. RHE).

Catalysts 68C to 73C were prepared by carbiding a reduced coprecipitated 3 Ni/Co alloy at different temperatures and times. A summary of the preparative conditions and the activities is given in Table XXVIII.

Contraction of the second s

From Table XXVIII it can be seen that at 240° C the activity decreases with increasing time of carbiding. It is possible that at 240° C no carbide was formed and that progressive sintering of the sample occurred. At 260° C the exposed samples exhibited an increase in activity with carbiding time. It would appear that the first sample (72C) was already substantially sintered after 24 hours; (its activity was below that of the initial sample (73C) at 240° C). The subsequent increase in performance can be attributed to carbide formation.

The behavior of the inducted samples does not follow the same pattern. The performance of the catalysts carbided at 240° C for 24 hours also showed low activity, but the 72 hour sample (70C) gave 146 ma/cm² at 750 mv <u>vs</u>. RHE. Catalysts 68C carbided for 120 hours gave a lower activity of 30 ma/cm². Although attempts to reproduce the results obtained with 70C were unsuccessful, duplicate measurements on the rest of the series confirmed the activity pattern described above. The level of activity in this second examination was lower than that of the first, probably related to the total time of exposure of the catalyst to air (~ 2 weeks) before the second tests were carried out.

Tests on catalyst 50R, a 3 Ni/Co alloy prepared in an almost identical manner to the starting material for the carbides 68C to 73C, demonstrated an activity of 225 ma/cm² at 600 mv. This is much higher than the results for the carbides, excepting the unconfirmed figure for 70C.

Another series of compounds tested were the alloys, carbides and nitrocarbides of 3 Ni/Au, Ni/3, 3 Ni/Pt, Ni/3 Pt, and 3 Ni/Ag; and the 3 Pd/Ag, and Pd/Ag alloys. The silver palladium alloys 3 Pd/Ag and Ag/Pd showed very high currents (> 300 ma/cm^2) at 750 mv vs. RHE, but activity at 950 mv (of the order of 5 ma/cm²) was lower than that observed with Pt or Au/Pd alloys. This is in accord with the results presented for solid electrodes of these alloys in the Fourth Quarterly Report of this contract. The 3 Ag/Pd alloys showed better, but still low, activity at 950 mv; however, the current at 750 mv was much reduced (190 m /cm²).

- 148 -

The second s

The Ni/Au alloys showed disappointing activity, with the Ni/3 Au alloys giving lower activity than the 3 Ni/Au alloys. This surprising result was reproduced in a re-examination at Tyco with electrodes of different PTFE content and in measurements made at the Bureau of Mines. The carbides and nitrocarbides of 3 Ni/Au were much less active than the parent alloy; the same compounds of Ni/3 Au were marginally more active $(4 \text{ ma/cm}^2 \text{ compared with } 1 \text{ ma/cm}^2 \text{ at } 750 \text{ mv vs. RHE})$ than the alloy.

The Ni/Pt alloys showed a very much lower activity than might be expected for a Pt based catalyst. The series of materials showed the same pattern of activity, as has been described before, of alloy > carbide > nitrocarbide. As with the Ni/Au alloys the activity of the nickel rich alloy was greater than that of the Ni/3 Pt alloys. The 3 Ni/Ag catalysts were very similar in performance to the 3 Ni/Au catalysts.

The gold palladium alloys showed promising activity; however, the performance level is well below that observed with a good Pt catalyst or the better examples of palladium gold prepared at Tyco. The carbide and nitrocarbide of 3 Pd/Au showed lower activity than the alloy. The range of alloy compositions 3 Pd/Au, Pd/Au and Pd/3 Au did not show the exact pattern of activity established with solid electrodes. The 3 Pd/Au alloy showed the highest activity, but the activity of the Au/Pd catalyst was below that of the 3 Au/Pd. This behavior can be accounted for in terms of differences in the structure of the finely divided catalyst.

The silver platinum (3 Ag/Pt) catalyst showed much lower activity than might have been expected for a platinum based catalyst.

SECTION 4

CATALYST LIFE TESTING

I. INTRODUCTION

T

In order to verify the activity for O_2 -reduction of catalysts tested as floating electrodes in the previous phase of this program, as well as to check for possible long term degradation, it was necessary to life test the various materials investigated.

One of the first steps in this procedure was the development of techniques for fabricating sufficiently large electrodes and facilities to handle them. Previously, electrodes had been made on the order of $5-10 \text{ cm}^2$, sufficient for one cm² test pieces needed for the floating electrode tests. For life testing it was decided that 50 cm^2 electrodes would be used. This required both modified techniques for making electrodes and a larger sintering oven.

In order to approach practical fuel cell conditions as closely as possible, a working fuel cell design was chosen rather than a driven cell. The particular design chosen, a reservoir cell, although impractical in size, weight, volume, etc., ensured that the catalyst material rather than the fuel cell system was being tested. The cell is essentially an asbestos matrix cell with special provisions for electrolyte control.

One of the most significant problems in extended fuel cell operations is the controlled removal of product water. Inadequate control results in flooding or drying out of the electrolyte matrix. A frequently used method of control employs the continuous flow of one or both gases at a controlled rate to remove the excess moisture. Other techniques which have been tried are flowing electrolyte systems, wicking arrangements, and the vapor pressure control system of Allis Chalmers.

The free electrolyte system requires very special electrodes and cell construction not suited to our present tests. The continuous gas flow system is simply constructed but somewhat difficult to control. The vapor pressure control system is easier to control but is very sensitive to leaks and is still prone to the problem of irreversible electrolyte loss during extended operation.

The fuel cell life test system was designed to take advantage of each of the above systems to yield a simple but more reliable testing device. The large reservoir of electrolyte, with its surface just below the gas side of the H₂ anode, maintained a constant water vapor pressure in the anode space. Since the O₂ electrode was dead-ended, this vapor pressure defined the concentration of the electrolyte in the cell in the same manner as the Allis Chalmers system.

The concentration of electrolyte in the reservoir was relatively unaffected by fluctuations in the water removal rate. Water was removed at a known rate in the H_2 exhaust. When deviations from the normal operating conditions resulted in loss of electrolyte, porous nickel wicks in contact with the anode and the electrolyte reservoir permitted the slow replacement of KOH.

Thus the reservoir cell simulated a free electrolyte system without the interface problem and had the advantage that it reduced the gas flow rate sensitivity of the water removal mechanism.

II. PREPARATION OF LARGE ELECTRODES

The first requirement for making large electroder was a larger sintering oven. This was accomplished by constructing a closed "drawer" device which could be moved in and out of a standard oven through a hole in the door. This chamber was constructed of thin gauge aluminum with a nitrogen preheater on the outside and a gas distribution system inside. Electrodes (12" x 12" max) were placed in the chamber through a door on the front and the chamber was flushed with nitrogen for about 15 minutes. The chamber was then pushed into the preheated oven for the Teflon sintering program.

Two platinum catalysts — Pt(a) and Pt(b) — (Table XXIX) are samples of the same electrode preparation: the former was sintered by our established method in the small sintering oven and the latter, in the new oven designed to accommodate large electrodes. The large oven gave a minimum warm-up time of 8 minutes to $275^{\circ}C$ and cool-down time of 12 minutes. These times are greater than those of the small oven, but it is apparent from the results in Table XXIX that in the case of Pt there was no detrimental effect. This was confirmed with several large electrodes, also listed in Table XXIX.

Another problem related to large electrode fabrication is the method of distributing the catalyst on the screen. A number of methods were described in section 3, such as spraying, brushing, rolling or spreading. For the massive screening programs described in section 3, the spreading technique was chosen because of the simplicity and economy in making the very small electrodes required. It was found, however, that this technique was very difficult to scale up, especially with regard to uniformity of distribution. Consequently the rolling method was chosen and was used to prepare all electrodes except the Ni₃C (which had to be spread, at the cost of uniformity, due to its high bulk density).

The catalyst preparations made into large electrodes are listed in Table XXX, along with the results of a floating electrode test of one $\rm cm^2$ of the outer edge of the large electrode. Of the Pd-Au alloy preparations, only the formaldehyde preparations were deemed sufficiently active to warrant further testing.

Most of the 40 large electrodes prepared, with the exception of the nickel carbide, were quite active — between 2 and 5 ma/mg. The nickel carbide preparation performed poorly compared with the other catalysts, as expected, and also in comparison to earlier Ni₃C preparations. However, of the 32 preparations of Ni₃C, only about 3 were successful, i.e. ~ 100 ma/cm² at 750 mv.

A CONTRACTOR OF A CONTRACTOR A CONTRA
III. LIFE TESTS

A. Experimental

Eight reservoir type cells were set up for life testing. The individual test station is conventional in design (see Figs. 23-26), providing for the control and measurement of gas pressures and flow rates and for the collection and measurement of the water produced. Particular attention was paid to carrying out the tests under realistic conditions but under circumstances (not necessarily feasible in a practical cell) that avoid the more common failure modes of a H_2/O_2 cell. Decay in performance can then be directly attributed to the cathode catalyst.

Maintaining the water balance is probably the most critical variable in the operation of a matrix cell. This was achieved by having a large reservoir of electrolyte immediately behind the anode (see Fig. 26). This reservoir defined the water vapor pressure in the anode gas space (i.e. no presaturation was necessary) and therefore controlled the water content of the electrolyte trapped in the matrix. Since the reservoir electrolyte concentration could not change very rapidly even with relatively high H_2 flow rates, the water vapor pressure remained constant for relatively long periods of time (say several hours). An effective water balance could then be maintained by comparing the total amount of water removed with that produced (calculated from the current-time curve) and by making the necessary adjustments in the gas flow rates. Product water was removed primarily by the flow of excess hydrogen. A further refinement was the provision of porous nickel wicks from the electrolyte reservoir to the matrix. Then, in the event of loss of KOH from the matrix (e.g. lost as a result of gross deviations in the water balance which result in drowning), the KOH could be replaced by diffusion through the wicks.

The reservoir cell, therefore, simulated a free electrolyte system but without the associated interface problem and had the advantage that it reduced the gas flow rate sensitivity of the water removal mechanism.

and the second second second

The catalysts were tested as PTFE bonded electrodes, 50 cm^2 , formed on gold plated expanded nickel screen. The electrolyte was 35% KOH and the cells were run at 80°C. In all cases the anode was a commercial platinum electrode (American Cyanamid AB-40). This electrode with a Pt loading of 40 mg/cm² on a gold plated nickel screen is specifically designed to give long life and reliability.

B. Preliminary System Tests

Two cells were set up initially, one with an American Cyanamid AB 4X cathode, the other with a cathode made at Tyco from a commercial platinum black (37 mg/cm^2). The anodes of both cells were American Cyanamid AB-40 electrodes.

Both cells were run with 40% KOH in the temperature range 77 to 79°C. The patterns of performance for both cells are shown in Figs. 27 and 28. The principal difference between the two life tests is that cell #2 failed three times during the course of the test but was successfully restored to the original performance level by blowing out the cathode vent lines. This action removed large quantities of electrolyte (compared with the amount of water normally removed by the gas glow) and accounts for the difference between the theoretical and measured quantities of water shown in the plots in Figs. 27 and 28. The problem was considered to be due, in part, to the difficulty of controlling the low gas flow rates, and the pressure differential across the cell, with the needle valves originally fitted on the vent lines. These were replaced to alleviate this difficulty. It is also possible that the electrolyte accumulated in the cathode space because of some transport mechanism (e.g. electro-osmosis) that is a critical function of the structure and PTFE content of the electrode. This accumulation of electrolyte could be avoided by applying a pressure differential across the cell. This was difficult to control in the initial test because of the difficulties associated with the adjustment of the needle valves in the vent line.

Maximum current from the cells was < 3A until copper leads were added as the current carriers to the load devide (a transistor bias circuit)

in place of the stainless steel gas lines. To improve current collection at the cathode, the nickel screen current collectors and the cell back plate were gold plated. These changes permitted loads of up to 8 amps (160 ma/cm^2) . In order to make the modifications listed above, tests on cells #1 and #2 were terminated after about 250 hours.

After these modifications were made, all eight cells were gradually put into operation. Since the temperature specification was lowered from 90° to 80°C, the KOH concentration was also lowered from 40% to 35%. The cells were operated continuously at about 5 amps (100 ma/cm²). For the sake of stability, the cells were operated below the optimum performance level. Maximum performance was obtained by allowing electrolyte to flood the oxygen cavity, with simultaneous removal by excess oxygen flow. This behavior can be explained by assuming that electrolyte pumping without removal caused deterioration by flooding, while if pumping was avoided by excess oxygen pressure, the oxygen electrode was not optimally wetted by electrolyte and the performance decreased. Periodically the cells were brought up to maximum performance for purposes of comparison.

The following materials were life tested as oxygen reduction catalysts.

 1570 hours.
- (6) Pd-Au 40/60 #F-13 (L-1) 28 mg/cm^2 , 20% PTFE

Operated for 3000 hours to investigate the effects of palladium alloy corrosion.

(7) Pd-Au 50/50 #F-15 (L-1) 23 mg/cm², 20% PTFE

Test terminated at 1250 hours in order to begin testing other materials.

- (8) Pd-Au 70/30 #F-17 (L-1) 24 mg/cm², 10% PTFE 1610 hours.
- (9) Pd-Au 60/40 + 50 wt % Ag₂O 32 mg/cm², 20% PTFE 1470 hours.
- (10) Au-Pt-Pd (B. O. M.) #107-R-(L-1) 39 mg/cm², 20% PTFE
 1584 hours.
- (11) Ag-Pt-Pd (B. O. M.) #100-R-(L-1) 38 mg/cm², 20% PTFE -1584 hours.
- (12) Ni₃C (B. O. M.) #54-C56 mg/cm², 20% PTFE

Terminated at 646 hours to begin testing a second sample of Ni₃C.

(13) Ni₃C (TYCO) #69 (L-1) 25 mg/cm^2 , 10% PTFE

Terminated after 530 hours due to low performance.

C. Results

The results of the life testing are shown graphically in Figs. 29-31. Voltage current curves were taken periodically (Table XXXI), and cell voltages at 100 ma/cm^2 are given in the figures. None of the cells tested failed, although some were terminated before 1500 hours due to low performance or redundancy.

The best results were obtained with the Pt-Au 70/30, Pt-Ag 30/70, and Pd-Au 40/60. The platinum-gold alloy is particularly promising since it showed a higher performance level than pure platinum at the same loading (Tyco Pt) and higher than Pt at twice the loading (AB-40). Since Pt-Au was one of the last materials tested, there was not sufficient time to prepare and test other alloy compositions. The one alloy tested, Pt-Au 70/30, corresponds to the peak in Figs. 6-9 (section 2) of potential <u>vs</u>. composition for the Pt-Au series (screening-solid electrode).

The Pd-Au 40/60 alloy is also interesting both for its performance which was comparable to platinum and for its apparent corrosion resistance. After 3000 hours of operation the performance level was only slightly below that of platinum. The performance of the other Pd-Au alloys was somewhat erratic but within the range of platinum performance nonetheless.

The Pt-Ag electrode which was a simple mixture of Pt and Ag_2O powders was very successful, indicating the importance of structural effects. The performance of the Pt-Os electrode was fair.

The noble metal mixtures prepared by the Bureau of Mines, Au-Pt-Pd and Ag-Pt-Pd, performed wellbut were not exceptional in view of the high loading required for their fabrication.

The nickel carbides, Bureau of Mines and Tyco preparations, showed low performance and deterioration (not as much as found in the floating electrode tests, however).

CHANNE AN

SECTION 5

A MATHEMATICAL TREATMENT OF THE POROUS PTFE BONDED ELECTRODES

I. INTRODUCTION

The theory of porous electrodes has been the object of many publications. A general discussion of the behavior of fully flooded and gas diffusion porous electrodes both for steady state and transient responses can be found in a recent monography by De Levie⁽¹⁹⁾. The present treatment is concerned only with the steady state behavior of gas diffusion electrodes, which although studied less than flooded electrodes, have also been the subject of attention in the last few years.

Four main models have been currently used to explain the behavior of the gas diffusion electrode: the Simple Pore Model, the Thin Film Model, the Surface Migration Model, and the Dual Scale of Porosity Model.

Two comments should be made at this point. First, the applicability of a certain model will depend on electrode structure; thus it can be expected that a model which applies to a Teflon bonded electrode will not apply to a Bacon sintered electrode and vice versa. Second, many of the models are microscopic models concerned with one element of the electrode producing the current, (such as a thin film or a finite contact meniscus, etc.). While the relationship between theory and the results obtained with the model system is straightforward, the way in which the electrode is composed by the simple elements is usually not clear at all. Thus a comparison between theory and results obtained with an <u>actual electrode</u> is virtually impossible. A few models, on the other hand, are macroscopic and treated as continuum systems. The application of these models is limited by their abstract nature. From this point of view, our model is an hybrid, with a microscopic consideration of elements (which are easily visualized in the total electrode) and with a macroscopic treatment of the elements of the electrodes ('flooded cylinders ').

- 187 -

A. The Simple Pore Model

This model as developed by Austin, et al.⁽²⁰⁾, is a modification of the old theory⁽²¹⁾ of the three-phase boundary according to which gas, metal and electrolyte came in contact in a boundary line.

In this model, as in the older one, the electrolyte does not cover the walls of the pore with a thin film, but its surface forms practically a 90° angle with the walls of the pore. In contrast to the old model, the gas, after diffusing through the pore to the electrolyte surface, dissolves and is transported to the submerged metallic electrode surface where it is consumed.

A similar model applies, according to Austin and Almaula⁽²²⁾, to the Teflon bonded electrode. These authors suggest for this electrode that only a thin layer near the plane electrode-electrolyte surface is wetted and takes part in reaction. Limiting currents and polarization are due to mass transfer of dissolved hydrogen to submerged platinum-black particles. According to these authors, only 2 - 5% of the electrode area is wetted. This is in contrast to our experiments⁽²³⁾ which show almost 100% wetting of the electrode surface area.

Srinivasan, Hurwitz and Bockris⁽²⁴⁾ have treated a one-dimensional Simple Pore Model in presence of activation, concentration and ohmic polarization. They suggested that a circulating system would greatly reduce concentration polarization and improve performance.

B. The Thin Film Model

According to Will^(25, 26) the walls of a pore are covered by an electrolyte film. Reactant gas diffuses <u>across</u> the film and reacts on the pore wall (above the electrolyte bulk). Ionic migration <u>along</u> the electrolyte film defines the current distribution along the length of the pore and limits the length which is effective for current production.

Will has treated this model mathematically⁽²⁶⁾ for the case of diffusion and ohmic control and has experimentally⁽²⁵⁾ confirmed his conclusions using a pre-wetted, half immersed Pt-wire in H_2SO_4 under H_2 atmosphere. These conclusions are as follows:

- 188 -

(1) At polarizations smaller than 10 mv, 99% of the current is produced in a zone of 0.35 mm from the electrolyte meniscus.

(2) For polarizations smaller than 10 mv, a linear dependence of the total current on the applied potential is calculated which checks quantitatively with his experimental results on half immersed bright Pt electrodes in 8 N $\rm H_2SO_4$.

(3) For polarization larger than 100 mv the current voltage curve is the type i = $K \sqrt{E}$.

(4) The relative contributions of meniscus (if meniscus is assumed in addition to film) to the total current depend on film thickness and electrolyte concentration. For a film 1 μ thick 8 N H₂SO₄ and E = 0.4 v, the meniscus contributes 0.26 ma and the film 1.16 ma.

(5) The reaction zone is confined to a narrow band close to the upper meniscus edge. In the numerical example given in 4, 0.35 mm of meniscus and 0.38 mm of film are responsible for 98% of the total current.

(6) For a half immersed electrode, a film thickness of 1.5 μ is deduced.

In a more recent publication (27) Will has made confirming measurements using horizontal electrodes with rather thick (1 mm) electrolyte films. He concludes that considerable stirring ought to exist, to explain the lower than predicted concentration gradients <u>along</u> the film. It is questionable, however, whether the conclusions reached with these rather thick films can be scaled down to thin films. In addition, concentration gradients can be explained by a "distillation mechanism" (see ref. 33 and our assumption no. 4) on page).

Iczkowski⁽²⁸⁾ introduced, in his treatment of the Thin Film Model, activation polarization in addition to diffusion and ohmic polarization. He solved numerically his equations for the O_2 -reduction in NaOH on Ni. Rockett and Brown⁽²⁹⁾ also treated the complete case for the oxygen electrode of the Bacon fuel cell.

- 189 -

Srinivasan and Hurwitz⁽³⁰⁾ solved numerically the equations of the Thin Film Model with simultaneous activation, concentration and ohmic polarization using dimensionless parameters which allow rather general application.

Lindstrom⁽³¹⁾ and Lindholm et al.⁽³²⁾, have applied the Thin Film Model to porous electrodes of the Bacon type. An important contribution of this work is the consideration of transport limitations in gas phase. Differences of polarization between H_2 - O_2 and Ar- O_2 mixtures at high drains confirm the importance of this limitation. This limitation will be important under certain conditions of current drain, gas dilution, and electrode geometry. It is interesting to note that conductivity and volume measurements of the electrolyte in the pore, as well as the effect of pressure differential on current, are interpreted by the Swedish workers as a "thinning out" of the film at higher pressures. The possibility that pressure may affect large amounts of electrolyte enclosed in small pores is not considered.

Bennion and Tobias⁽³³⁾ have studied the O_2 -electrode according to the Thin Film Model under consideration of axial diffusion of electrolyte. These authors considered also the possibility that water transfer from one end of the film to the other may occur through the gas phase.

C. Variants to Thin Film Model

Models considering the shape of a meniscus can be considered as half-way between the Thin Film Model and the Simple Pore Model. An example is to be found in the work of Cahan⁽³⁴⁾. This work can be discussed better by separating (1) the theory and experiments on "slit cell," (2) the extension to porous electrodes, and (3) the work on thin electrodes.

(1) <u>Slit cell</u>. This work is limited to the study, experimentally and theoretically, of the behavior of two partially immersed, parallel, smooth electrodes in an atmosphere of reactant gas. Cahan postulates, based on optical measurements, that a continuous Thin Film does not exist and proposes a Finite Contact Angle Model in which the current is drawn from the meniscus edge. The mathematical treatment, after suitable simplifications, is very similar to that of a Thin Film Model in presence of activation⁽²⁸⁻³⁰⁾ but taking into account the geometry of the meniscus. A numerical solution

- 190 -

using a computer program has been obtained for H_2 -oxidation and O_2 -reduction on Pt in 1 N H_2SO_4 . The theory agrees with the experimental results for the <u>slit cell</u> (although it should be noted that considerable uncertainty exists with regard to the i_0 of both H_2 - and O_2 -electrode reaction on Pt electrodes in acid, so that this i_0 could be considered as a calibration factor). Other conclusions reached by Cahan are as follows:

- (a) That current is proportional to square root of C (or p).
- (b) That current-potential curves are almost linear.
- (c) That the current in the slit cell is produced in a very small fraction of meniscus 10^{-4} to 10^{-5} cm from tip.
- (d) That in some cases a "meniscus heating effect" can be observed.

(2) Extension to porous electrodes. Throughout the discussion of the behavior of the slit cell there is a tendency on Cahan's part to extend the conclusions to porous electrodes. Thus, from fact that only 10^{-4} to 10^{-5} cm length, from the tip of an ideal single meniscus of the slit cell is utilized to produce current, Cahan concludes that "99% or more of a uni-formly distributed catalyst in a porous electrode is wasted, being out of the area of prime activity " ⁽³⁴⁾.

We do not find any justification for the extension of the theory of a single very special meniscus to a porous electrode. Our work on the "flooded agglomerate model" of the Teflon bonded electrode will show that in some cases almost 100% utilization of heavily loaded electrodes is possible. Indeed, the experimental results for these electrodes can be explained better by assuming high utilization of catalyst.

(3) Work on thin electrodes. Electrodes consisting of a 50 Å layer of platinum (250 μ g/cm² or less) deposited on Vycor have shown very high electrochemical performance as H₂-electrodes. These findings are constructed by Cahan as a confirmation that the real porous electrode works according to a Finite Contact Angle Model. We think that this work reflects the high exchange current of the hydrogen reaction and <u>relatively</u> good transport conditions. Such a thin structure could indeed be used as H₂-electrode

<u>in acid</u> if the problems of stability, H_2O removal and chmic contact could be solved. From consideration of the surface area available in 50 Å films and the exchange current of O_2 -electrode, it seems to us that a thin (50 -200 Å) O_2 -electrode, having the same performance as that of presently available electrodes is impossible using any of the known catalysts.

Borucka and Agar⁽³⁵⁾ have also treated the case of a defined meniscus using an electric conductance analog.

D. The Surface Migration Mechanism

Migration of hydrogen on the surface of electrodes has been suggested by several authors (36-43). It seems, however, that the surface diffusion coefficient determined by independent methods is too low (38) to contribute considerably to mass transport.

E. Double Scale of Porosities Model

Burshtein and co-workers⁽³⁹⁾ have treated the Bacon type electrode, assuming that there is a spectrum of porosities, so that small pores are flooded -- a model theory initiated by Markin ^(24, 25). Electrodes with an emphasized double scale of porosities have been constructed and tested experimentally. The fraction of flooded pores is adjusted by electrode design and by regulation of pressure differential. Flooding of small pores increases the ionic conductivity across the electrode and results in a deeper utilization than with the Thin Film Model. It should be noted that the experimental results of Brown and Rockett⁽³⁸⁾ with so-called "flooded electrodes" and the effect of pressure on activity observed by Lindstrom^(31, 32) could be used to confirm the "double scale of porosity model," although these authors give a different interpretation.

Burshtein and co-workers in their statistical treatment of the electrode neglect the diffusion of dissolved species and use a linear relationship between local current density and voltage. They are unable to prove or disprove their theory based on the experimental data.

A quantitative treatment for a somewhat related model has been given by Grens II $^{(42)}$. Grens considers gas filled macropores and electrolyte filled micropores. The electrode is represented by two one-dimensional continuum systems (a macro- and a micro-pore system) which are joined by a series of "linking pores," the length of which is short compared with the length of the micropores. Some limitations of this treatment (which are not present in our treatment) are that diffusion is assumed to be linear and that migration of ionic species is considered. (It is <u>implicitly</u> assumed that concentration equalization in the micropore phase is not possible by evaporation and concentration; i.e. Q-term of ref. 17 is unity.) The diffusion of reactant gas is considered along the transveral direction of the electrode; no gas diffusion in the micropore phase perpendicular to the micropore/macropore interface is considered. In effect, the thickness of flooded areas does not appear in treatment. Also, link pores are assumed, the dimensions of which are arbitrarily selected.
II. THE FLOODED AGGLOMERATE MODEL OF THE TEFLON BONDED ELECTRODE

A. Qualitative Description

The Teflon bonded electrode seems to us an ideal case of structure with double scale of porosity. According to a qualitative description by Giner (43, 44) the working mechanism of this structure can be explained by assuming, as shown in Fig.32, that the catalyst particles form porous (and electronically conductive) agglomerates which, under working conditions, are flooded with electrolyte. The catalyst agglomerates are kept together by the Teflon binder which creates hydrophobic gas channels. As current is drawn from the electrode, reactant gas diffuses through the channels, dissolves in the electrolyte contained in agglomerates, and after diffusing a certain distance, reacts on available sites of catalyst particles.

This qualitative explanation of the working mechanism based on the flooded agglomerate is confirmed by our own measurements which show (1) that the catalyst area in contact with electrolyte is the same when the Teflon bonded electrode is working as a gas diffusion cell electrode as when it is completely flooded with electrolyte *, (2) that the microporosity of the agglomerates is about 90%, i.e. 10% catalyst and 90% electrolyte. (Microporosities of about 80% have also been measured by Horowitz⁽⁴⁵⁾, who also assumes the same qualitative model.)

B. Mathematical Treatment

One way of quantitatively treating this working mechanism is to substitute flooded agglomerates by a porous cylinder of radius r_0 and length h (as shown in Fig. 33), in which catalyst particles and electrolyte are homogeneously dispersed as a continuum. (Microporosity, θ , is defined as the volume of electrolyte per total volume of cylinder.) The porous cylinder is perpendicular to the external surface of the electrode. During operation, gas arrives at the cylinder in a direction perpendicular to its axis and diffuses to its center along the coordinate r, with simultaneous bulk re-

This is conflict with the value of 2 to 5% reported by Austin and Almaula⁽²²⁾.

;

æ

l

-

- 196 -

1477 - ----

action on catalyst particles in the diffusion path. Ionic current is conducted in the direction x parallel to the cylinder axis.

1. Assumptions

For the mathematical treatment we assume that:

(1) The electrode is made up of a number of porous cylinders of catalyst flooded with electrolyte. These cylinders are perpendicular to the external surface of the electrode.

(2) Electrolyte and catalyst are homogeneously mixed

as a continuum.

(3) The intrinsic activity of the catalyst is constant throughout the cylinder.

(4) Equilibration of electrolyte concentration in cylinders occurs efficiently via an evaporation-condensation process.

(5) The local current density is directly proportional to the local concentration of reactant; i.e. an expression such as eq. (1) is pertinent.

(6) The voltage in the cylinder changes only in the axial direction and diffusion of dissolved gas occurs only in the radial direction.

(7) There are no transport limitation in the gas phase.

(8) There are no kinetic limitations in the process of

gas dissolution.

(9) There is no electronic iR-drop in cylinders.

(10) There is no convention inside the cylinders.

In order to extend the theory of a single cylinder to the complete electrode we will further assume at this point that:

(11) The radius of all porous cylinders has the same value. (Under these conditions the number of cylinders per cm² of electrode (N) is related to a measurable macroscopic factor, which we will call macroporosity (β) , by the expression $\beta = 1 - N\pi r_0^2$).

- 197 -

2. General Treatment

The local current density i (r, x), i.e. current per unit of "real area," at a point (r, x) in the cylinder is assumed to be expressed by equation:

$$i = i_0 \left[\frac{C(x, r)}{C_0} \exp \left[\alpha z \eta(x) / \phi \right] - \exp \left[-(1 - \alpha) z \eta(x) / \phi \right] \right]$$
(1)

The diffusion of the gas in the cylinder (with a simultaneous bulk consumption given by $i\gamma/nF$, $\gamma =$ surface to volume ratio) follows the 2nd Fick's law for cylindric diffusion:

$$\frac{\partial^{2}C(x, r, t)}{\partial r^{2}} + \frac{\partial}{D}\frac{1}{r}\frac{\partial C(x, r, t)}{\partial r} - \frac{i\gamma}{nF} = \frac{\partial C(x, r, t)}{\partial t}$$
(`)

At steady state:

$$\frac{\partial C(x, r, t)}{\partial t} = 0$$

and therefore:

$$\frac{1}{D} \left\{ \frac{\partial^2 C}{\partial r^2} + \frac{1}{r} \frac{\partial C}{\partial r} \right\} = \frac{i\gamma}{nF} = \frac{\gamma i_0}{nF} \left\{ \frac{C(x,r)}{C_0} \exp \frac{\alpha z \eta(x)}{\phi} - \exp \frac{(\alpha - 1)z \eta(x)}{\phi} \right\} (3)$$

Boundary conditions:

$$\frac{\partial C}{\partial r} = 0$$
 at $r = 0$, $C = C_0$ at $r = r_0$

Californi Andrea Parasan

- 198 -

Charles States and

The solution of this equation for the r-variation of C is straightforward:

 $C = C_0 \exp - \frac{z \eta}{\phi} +$ (the solution of the homogeneous equation

$$\frac{\partial^{2}C}{\partial r^{2}} + \frac{1}{r} \frac{\partial C}{\partial r} - \left[\frac{\gamma i_{0}}{n F D C_{0}} \exp \frac{\alpha z \eta}{\phi}\right]C = 0 \quad (4)$$

The solution of the homogeneous equation can be expressed in terms of modified Bessel functions.

Since $\partial C / \partial r = 0$ at r = 0, the solution for C is:

$$C = C_{o} \exp - \frac{z \eta}{\phi} + k_{1} I_{o} \left(\left[\frac{\gamma i_{o} r^{2}}{n F \overline{D} C_{o}} \exp \frac{\alpha z \eta}{\phi} \right]^{\frac{1}{2}} \right), \quad (5)$$

where I_{0} is standard notation for the modified Bessel function of zero order and k_{1} is a constant.

 k_1 is fixed by the requirement that $C = C_0$ at $r = r_0$

$$k_{1} = \begin{pmatrix} C_{0} \left[1 - \exp - \left(\frac{z \eta}{\phi} \right) \right] \\ I_{0} \left(\left[\frac{\gamma i_{0} r_{0}^{2}}{n F \overline{D} C_{0}} \exp \frac{\alpha z \eta}{\phi} \right]^{\frac{1}{2}} \right) \\ k_{1} = \frac{C_{0} \left[1 - \exp - \left(\frac{z \eta}{\phi} \right) \right]}{I_{0} (q)}$$

$$(6)$$

or k

- 199 -

MANIA STRATE

Thus equation (5) gives the variation of C with the radius of the cylinder (ag₅ lomerate) at a given value of x. E (or η) is only a function of x (coordinate in the axis direction) according to ohm's law:

$$\frac{d\eta}{dx} = -\frac{j(x)}{\pi r_0^2 \kappa}$$
(7)

At the same time:

$$-\frac{dj(x)}{dx} = 2\pi\gamma\int_0^{r_0} irdr$$
 (8)

From equations (7) and (8):

$$\frac{d^2 \eta}{dx^2} = \frac{2 \gamma}{r^2 \sigma^{\kappa}} \int_0^{r_0} ir dr. \qquad (9)$$

The solution for C (equation (5)) can be used to solve equation (9) for η : Thus multiplying equation (3) by r d r and integrating gives:

$$\overline{D} r_{O} \left[\frac{\partial C}{\partial r} \right]_{r = r_{O}} = \frac{\gamma}{n F} \int_{O}^{r_{O}} i r d r \quad (10)$$

1

from (9) and (10)

$$\frac{d^2 \eta}{dx^2} = \frac{2 n F \overline{D}}{\overline{\kappa} r_0} \left(\frac{\partial C}{\partial r}\right) r = r_0$$

From solution (5):

÷

$$\begin{bmatrix} \frac{\partial C}{\partial r} \end{bmatrix}_{r=r_{0}} = k_{1} \begin{bmatrix} \frac{\gamma i_{0}}{n F \overline{D}C_{0}} \exp \frac{\alpha z \eta}{\phi} \end{bmatrix}^{\frac{1}{2}} I_{0}' \left(\begin{bmatrix} \frac{\gamma i_{0} r_{0}^{2}}{n F \overline{D}C_{0}} \exp \frac{\alpha z \eta}{\phi} \end{bmatrix}^{\frac{1}{2}} \right)$$
(11)

WHERE WE

Also $I'_{O}(x) = I_{1}(x)$, where I_{1} is the modified Bessel function of order 1, or if we use previous definition of q, the equation for η is

$$\frac{\mathrm{d}^2 \eta}{\mathrm{d} x^2} = \frac{2\mathrm{n} \,\mathrm{F}\,\mathrm{D}\,\mathrm{C}_{\mathrm{O}}}{\mathrm{r}_{\mathrm{O}}^2 \,\bar{\kappa}} \left[1 - \exp\left(-\frac{z}{\varphi}\eta\right)\right] \frac{\mathrm{q}\,\mathrm{I}_{1}(\mathrm{q})}{\mathrm{I}_{\mathrm{O}}(\mathrm{q})} \tag{12}$$

Boundary conditions $\eta = \eta_0$ at x = 0, $d\eta/dx = 0$ at x = h.

At this stage it is convenient to introduce scaled variables. Define this by $\eta' = \frac{\eta}{\eta_0}$, $x' = \frac{x}{h}$ where η_0 is the measurable overvoltage at the electrolyte.

$$\frac{\mathrm{d}^{2}\eta'}{\mathrm{dx'}^{2}} = \frac{2\mathrm{n}\,\mathrm{F}\,\overline{\mathrm{D}}\,\mathrm{C_{0}}\mathrm{h}^{2}}{\eta_{0}\,\bar{\kappa}\,\mathrm{r_{0}}^{2}} \left[1 - \exp\left(-\frac{z\,\eta_{0}}{\phi}\,\eta'\right)\right] \frac{\mathrm{q}\,\mathrm{I_{1}}(\mathrm{q})}{\mathrm{I_{0}}(\mathrm{q})} \tag{13}$$

Boundary conditions: $\eta' = 1$ at x' = 0, $d\eta'/dx' = 0$ at x' = I.

It can be seen that equation (13) expresses η' only as a function of x' and a series of measurable constants. This equation can be solved with a relatively simple computer program. From this computer program we want to know:

- (a) The local current at constant x' as a function of the cylinder radius. This is a measure of the depth utilization of the cylinder (or agglomerate), which is controlled mainly by diffusion.
- (b) The current production at different values of x'. This is a measure of the depth of utilization of the electrode, which is controlled mainly by ohmic drop.
- (c) The current density per unit area of electrode: i.e. the measurable current density.

- 201 -

<u>Depth Utilization of Cylinder.</u> The local current can be obtained from equation (1) since we know C (x, r) and η (r) from equations (5) and (13). Thus substituting solution (5) in equation (1) one obtains:

$$i = \frac{i_{o} k_{1}}{C_{o}} \left(\exp \frac{\alpha z \eta}{\phi'} \right) I_{o} \left(\left[\frac{\gamma i_{o} r_{o}^{2}}{n F \overline{D} C_{o}} \exp \frac{\alpha z \eta}{\phi'} \right]^{\frac{1}{2}} \frac{r}{r_{o}} \right)$$
(14)

or

 $i = p I_{O} \left(q \frac{r}{r_{O}} \right)$ (15)

where p and q, which we will call distribution parameters, are suitably defined. From q the utilization of the catalyst as a function of r for a given x can be obtained, as shown in Fig. 34.

<u>Depth Utilization of Electrode.</u> Other information of a pertinent nature is the current production for different cross sections of the cylinder. This current is, of course, dj(x)/dx. The total current per cylinder across the surface x = constant, is

$$j(x) = -\pi \bar{\kappa} r_0^2 \frac{d\eta}{dx} , \qquad (16)$$

or expressed in nondimensional variables.

$$j(x) = - \frac{\pi \bar{\kappa} r_0^2 \eta_0}{h} \frac{d\eta'}{dx'}.$$
 (17)

The current derivative:

$$\frac{d}{dx} = -\frac{\pi \bar{\kappa} r_0^2 \eta_0}{h^2} \frac{d^2 \eta'}{dx'^2}$$
(18)

Mrs Server L.

Electrode Current Density. The current density per unit area of electrode surface I(o) can be obtained from the total current of a cylinder j(o) by:

$$I(o) = j(o) \frac{1 - \beta}{\pi r_o^2}$$
(19)

$$I(o) = \frac{-\overline{\kappa} \eta_0 (1-\beta)}{h} \qquad \frac{(d\eta')}{(dx')}_{X'=0}$$
(20)

3. Application of the Model to Oxygen Electrode

In the first application of the model we have used the computer program to calculate (a) local current as function of cylinder radius, (b) current generated at different planes perpendicular to cylinder axis, and (c) measurable electrode current density.

The program, with pertinent comments, is presented in the Appendix.

We have fixed the following data which we feel is realistic for a Teflon bonded platinum electrode operating as oxygen electrode at 80° C in 30% KOH:

$$\eta_{0} = 0.3 \text{ volts}$$

$$\alpha = 0.5$$

$$n = 4 \text{ equiv/mol.}$$

$$D = 2 \times 10^{-5} \text{ cm}^{2}/\text{sec} \quad (\text{extrapolated from ref. 48})$$

$$\kappa = 0.75 \, \Omega^{-1} \text{cm}^{-1} \quad (47)$$

$$S = 20 \, \text{m}^{2}/\text{g} \quad (23)$$

$$w = 20 \times 10^{-3} \, \text{g/cm}^{2} \quad (23)$$

$$h = 0.02 \, \text{cm} \quad (23)$$

$$C_{0} = 5.5 \times 10^{-8} \, \text{mol/cm}^{3} \quad (46)$$

$$z = 1$$

$$(\oint = 0.032)$$

$$\rho = 20 \, \text{g/cm}^{3}$$

- 204 -

or

Indirect structural variables are:

 $\gamma = S \rho (1 - \theta) = 2 \times 10^5 \text{ cm}^2/\text{g} \times 20 \text{ g/cm}^2 (1 - \theta) = 4 \times 10^6 (1 - \theta) \text{ cm}^{-1}$ $\beta = 1 - \frac{W}{\rho h (1 - \theta)} , \text{ macroporosity, and}$

 $D = \Theta D$ and $\bar{\kappa} = \Theta \kappa$. (The tortuosity factor is taken as unity for the purpose of the present example.)

As variables we have taken microporosity $\,\theta$, cylinder radius r $_{0}$, and exchange current $\,i_{0}$.

The computer tabulations are reproduced in the Appendix. These tables were obtained for $\theta = 0.5, 0.7, \text{ and } 0.9, r = 10^{-3}, 10^{-4} \text{ and } 10^{-5} \text{ cm},$ $i_0 = 10^{-6}, 10^{-7}$, and $10^{-8} \text{ A/cm}^2 \text{ *}$. The columns of these tables show (a) position = x/h; (b) relative potential = $\frac{\eta}{\eta_0}$; (c) current in amps flowing through a plane x; (d) current derivative, i.e. current produced at the plane x; and (e) distribution parameter p, (see equation (15)), and distribution parameter q (see equation (15) and Fig. 34). At the end of each tabulation the measurable current density (in A/cm²) is shown. Table XXXII shows a summary of effect of θ , r and i_0 on electrode current density. In all cases, decreasing the radius from 10^{-3} to 10^{-4} cm has a large

In all cases, decreasing the radius from 10^{-5} to 10^{-4} cm has a large effect on current, but a further decrease below 1 micron has little effect on performance. This finding, of course, applies only under the diffusion conditions of this example.

According to Table XXXII current densities higher than 150 ma/cm^2 are obtained for $i_0 = 10^{-6} \text{ A/cm}^2$ and $r_0 \le 10^{-4} \text{ cm}$. For $r_0 \le 10^{-4}$ and $i_0 < 10^{-7}$ the current density is proportional to i_0 . These conditions correspond to high radial Pt utilization (small values of q). The exact range of high Pt-utilization will be discussed in the following.

* Our own work with smooth platinum in KOH solutions shows $i_0 = 5 \times 10^{-7} \text{ A/cm}^2 \text{ at } 80^{\circ}\text{C}^{(49,50)}$. When the Pt is well utilized, the current is also independent of microporosity (θ). This is due to the fact that in this range the current from cylinder is directly proportional to $(1 - \theta)$, (Table XXXII), and the number of cylinders is inversely proportional to $(1 - \theta)$.

A summary of the internal voltage drop as a function of θ , i_0 and r_0 is given in Table XXXIII which shows that in all cases the internal voltage drop is small. For $\theta = 0.9$ and $r_0 = 10^{-5}$ a voltage drop of only 11 mv between front and back of the electrode is observed, even if the current density is 386 ma/cm². Correspondingly, the current produced at the plane x' = 1 is only 10% lower than the current at x' = 0. For $\theta = 0.5$, on the other hand, the internal voltage drop is 55 mv and the current produced at the plane x' = 1, 58% lower than at the plane x' = 0. This relatively poor transversal utilization of the electrode with $\theta = 0.5$ explains in part why, for instance, at $i_0 = 10^{-6}$ and $r_0 = 10^{-4}$ the current for this value of θ is only half of the current when $\theta = 0.9$. The obvious solution of using electrodes of high degree of microporosity has to be re-examined after considering limitations of gas phase diffusion: Increase of microporosity (θ) at constant electrode loading (w) and thickness (h) results in an decrease of macroporosity (β) and therefore in a decrease of the residual volume. This volume includes volume of gas channels, of Téflon particles, and of wire screen, as shown in Table XXXIV. The fraction of gas volume in the residual volume is immaterial in the present treatment because we have assumed that diffusion in the gas phase is fast. But this assumption applies only under certain conditions of electrode structure, reactant gas concentration and current drain.

Table XXXV shows the value of the second distribution parameter which is a measure of the radial utilization of the agglomerates. The radial utilization is good when q is small. As shown in Fig. 34, the radial distribution is reasonably good for q < 1. Comparing the values of q in Table IV with the curves of Fig. 34 shows that for $r_0 \leq 10^{-4}$ and $i_0 \leq 10^{-6}$ radial utilization of catalyst in agglomerate is reasonably good.

4. Discussion Based on Approximations

When applying the model to the oxygen electrode, the potential changes very little along the cylinder in most cases (Table XXXIII). The current derivative is almost constant -- a related result since this is a function of η' .

This result could have been anticipated from an examination of the three nondimensional variables in the basic equation (13).

(a)
$$\frac{z \eta_0}{\phi} = 9.375$$
, or exp $\frac{\alpha Z \eta_0}{2\phi} \sim 10$
(b) $\left(\frac{\gamma i_0 r_0^2}{n F \overline{D} C_0}\right)^{\frac{1}{2}} \sim \left[\frac{i_0 r_0^2 (1 - \theta) \times 10^{13}}{\theta}\right]^{\frac{1}{2}}$
(c) $\frac{2n F \overline{D} C_0 h^2}{\eta_0 \bar{\kappa} r_0^2} \sim \frac{1.6 \times 10^{-9}}{r_0^2}$

The right hand side of equation (13) is small for the range of values of $i_{\rm O}$ and $r_{\rm O}$ of interest to us.

A valid approximation then is to suppose $\eta' = 1$ everywhere in calculating

$$\frac{\mathrm{d}^2\eta'}{\mathrm{dx'}^2}$$

as a small constant.

This makes the current derivative approximately a constant, and the end current j(0) is just the integral of this constant

$$j(o) = + \frac{\pi \bar{\kappa} r_0^2 \eta_0}{h} \frac{d^2 \eta'}{dx'^2}$$
(22)

- 211 -

The total current per unit area is

$$I(o) = \frac{2n F \overline{D} C_{o} h(1-\beta)}{r_{o}^{2}} \left[\frac{q I_{1}(q)}{I_{o}(q)} \right]$$
(23)

(The exponential term is neglected.) Where now

$$q = \left(\frac{\gamma i_{o} r_{o}^{2}}{n F \overline{D} C_{o}}\right)^{\frac{1}{2}} \exp \left(\frac{\alpha z \eta_{o}}{2\phi}\right) \sim 10 \left(\frac{10^{13} (1 - \theta) i_{o} r_{o}^{2}}{\theta}\right)^{\frac{1}{2}}$$

Further analysis can be made under the following approximations, which are not always valid.

(1) q is small.

This is good when $r_0 = 10^{-5}$, $i_0 = 10^{-7}$ but is wrong for $r_0 = 10^{-3}$, $i_0 = 10^{-6}$. For q small,

$$\frac{qI_1(q)}{I_0(q)} \simeq \frac{q^2}{2}$$

$$I(o) \stackrel{\sim}{=} \gamma i_{O}^{h} (1-\beta) \exp\left(\frac{\alpha z \eta_{O}}{\phi}\right) = S w i_{O}^{h} \exp\left(\frac{\alpha z \eta_{O}}{\phi}\right)$$
(24)

The electrode current density is independent of r_0 . It is dependent on C_0 through i_0 .

Total current increases linearly with i_0 , S and w.

Total current is independent of $\hat{\boldsymbol{\theta}}$.

The Tafel parameter b for the porous electrode is the same as for the smooth electrode.

The basic situation is one in which C is roughly uniform across the electrode, and the I_O Bessel function is roughly = 1 everywhere.

(2) q large.

Approximation valid when $r_0 = 10^{-3}$, $i_0 = 10^{-6}$.

Distribution parameter q is large, so that the Bessel function's arguments vary widely across the cylinder. C is then much larger near the outer surface than in the center, and catalyst is not being so well utilized.

q

$$\frac{qI_1(q)}{I_0(q)} \stackrel{\sim}{\simeq}$$

$$I(o) \simeq \frac{2h(1-\beta)}{r_o} (\gamma i_o n F \overline{D} C_o)^{\frac{1}{2}} \exp\left(\frac{\alpha Z \eta_o}{2\phi}\right)$$

or

$$I(o) = \frac{2 w}{\rho (1-\theta) r_{o}} (\gamma i_{o} n F \overline{D} C_{o})^{\frac{1}{2}} \exp\left(\frac{\alpha z \eta_{o}}{2\phi}\right)$$
(25)

This does depend on r_0 , increasing when r_0 decreases. It increases like $C_0^{\frac{1}{2}}$ and $i_0^{\frac{1}{2}}$, (over-all then current is proportional to C_0).

The Tafel parameter \underline{b} for the porous electrode is twice that for the smooth electrode.

Also:

I (o)
$$\propto \frac{\theta^{\frac{1}{2}}}{(1-\theta)^{\frac{1}{2}}}$$

i.e. increasing θ increases current.

- 213 -

C. Analysis Assumptions

The consideration of a Teflon bonded electrode with flooded agglomerates as a bunch of parallel flooded cylinders consisting of a continuum mixture of catalyst and electrolyte is a very simplified treatment of a very complex structure. Therefore, the applicability of the used assumptions is restricted to relatively narrow limits. It is necessary to know these limits in order to use the model safely in the pertinent cases and/or to modify the assumptions when we want to extend the model to other cases. An exact discussion of the assumptions and an extension of the application of the model by using less restrictive assumptions should be the object of future work. A preliminary discussion however will be given in the following:

1. Cylindric Configuration

The difference between a cylindric surface and any other surface as gas/agglomerate interface is reflected mostly on the accessibility of the interior of the agglomerate to diffusion. For comparison let's consider a porous <u>planar</u> agglomerate of a thickness $2 r_0$ perpendicaular to the external surface of the electrode.

Now instead of equation (2):

$$\frac{\partial^2 C}{\partial r^2} = \frac{\gamma i_o}{n F \overline{D}} \left\{ \frac{C(x, r)}{C_o} \exp \frac{\alpha z \eta}{\phi} - \exp \frac{(\alpha - 1) \eta}{\phi} \right\}$$
(26)

 $\therefore C = C_{0} \exp - \frac{z \cdot \eta}{\phi} + \text{ solution of the homogeneous equation}$ $\frac{\partial^{2} C}{\partial r^{2}} = \frac{\gamma i_{0}}{n C_{0} F \overline{D}} \left(\exp \frac{\alpha z \eta}{\phi} \right) C \qquad (27)$

This solution must be symmetric about r = 0.

$$C = C_{O} \exp - \frac{z \cdot \eta}{\phi} + k_{1} \cosh \left(\left[\frac{\gamma i_{O}}{n C_{O} F \bar{D}} \exp \frac{\alpha z \cdot \eta}{\phi} \right]^{\frac{1}{2}} \dot{r} \right)$$
(28)

WYSTER A PARTY OF

- 214 -

Since

$$C = C_{o} \text{ at } r = r_{o}, \ k_{1} = \frac{C_{o} \left[1 - \exp\left(-\frac{z\eta}{\phi}\right)\right]}{\cosh\left(\left[\frac{\gamma i_{o} r_{o}^{2}}{n C_{o} F \bar{D}} - \exp\left(\frac{\alpha z \eta}{\phi}\right)\right]^{\frac{1}{2}}\right)}$$
(29)
$$\frac{dj}{dx} = 2\gamma \int_{0}^{r_{o}} \text{idr} = 2n F \bar{D} \int_{0}^{r_{o}} \frac{\partial^{2} C}{\partial r^{2}} \ dr = 2n F \bar{D} \left[\frac{\partial C}{\partial r}\right]_{r = r_{o}}$$
$$= \frac{2n F \bar{D} C_{o}}{r_{o}} \cdot \frac{q \sinh q}{\cosh q} \cdot \left[1 - \exp\left(-\frac{z\eta}{\phi}\right)\right],$$
(30)

where
$$q = \left(\frac{\gamma i_o^2 r_o^2}{nF \bar{D}C_o}\right)^{\frac{1}{2}} \exp \frac{\alpha z \eta}{2\phi}$$
 as before.

With equation (7) converted to $\frac{d\eta}{dx} = -\frac{j(x)}{2r_0 \bar{\kappa}}$ (31)

$$\frac{d^2 \eta}{dx^2} = \frac{nF \tilde{D}C_0}{\kappa r_0^2} \left[1 - \exp\left(-\frac{z \eta}{\phi}\right) \right] \frac{q \sinh q}{\cosh q}$$
(32)

With the nondimensional variables as before

$$\frac{d^2\eta'}{dx'^2} = \frac{n F \bar{D} C_0 h^2}{\eta_0 \bar{\kappa} r_0^2} \left[1 - \exp\left(-\frac{z' \eta_0 \eta'}{\phi}\right) \right] \frac{q \sinh q}{\cosh q}$$
(33)

$$q = \left(\frac{\gamma i_{o} r_{o}^{2}}{nF \overline{D}C_{o}}\right)^{\frac{1}{2}} \exp \frac{\alpha z \eta_{o}}{2\phi} \cdot \eta'$$

- 215 -

Were Arever

The only difference between this and the case of cylindric geometry is the absence of the factor 2 on the right hand side, and the ratio of hyperbolic functions instead of Bessel functions.

The same nondimensional numbers appear.

Therefore with the same magnitudes of the physical variables as before, we would again have $d^2\eta'/dx'^2$ small and $\eta' \geq 1$ everywhere. Argue as before to

$$j(o) = \frac{2r_{o}\bar{k}\eta_{o}}{h} \frac{d^{2}\eta'}{dx'^{2}}$$
(34)

$$\sim \frac{2\mathrm{nFDC_oh}}{r_o} \left[\frac{q \sinh q}{\cosh q}\right] \tag{35}$$

$$I(o) = \frac{nF\overline{D}C_{o}h}{r_{o}^{2}} (1-\beta) \left[\frac{q \sinh q}{\cosh q}\right]$$

Case (I). q small, sinh q ~ q, $\cosh q \sim 1$:

$$I(o) \sim \gamma i_{o} h (1-\beta) \exp\left(\frac{\alpha z \eta_{o}}{\phi}\right)$$
(37)

 $\left[\frac{q \sinh q}{\cosh q}\right] \sim q^2$

(36)

which is identical with the previous result for the cylindrical geometry. This is a consequence of the full utilization of the electrode material.

Case (II). q large, $\sinh q \sim \frac{1}{2} e^{q}$, $\cosh q \sim \frac{1}{2} e^{q}$: $\frac{q \sinh q}{\cosh q} \sim q$ (38)

$$I(o) \sim \frac{h(1-\beta)}{r_o} (\gamma i_o n F \bar{D} C_o)^{\frac{1}{2}} \exp\left(\frac{\alpha z \eta_o}{2\phi}\right)$$
(39)

There is a factor 2 difference between this result and the previous one for cylindric diffusion which can be interpreted as a geometrical effect.

2. Continuum Distribution of Catalyst and Electrolyte

Such an assumption is acceptable if (a) the dimensions of the particles and pores making up the agglomerate are small compared with the radius of the agglomerate and (b) the dimension of the region where most of the current is produced is large compared with the dimensions of the catalyst particles and of the micropores. This second condition is of course more restrictive than the first condition and should suffice. For large values of q (i.e. for large values of i_0) the current is produced almost exclusively in the periphery of the cylinder; therefore, the continuum assumption can not be used for such a case as the hydrogen electrode.

As a consequence of the continuum distribution, a diffusion limiting current for an electrode of very high i_0 , such as the hydrogen electrode, cannot be obtained mathematically with our model. This is easy to understand because assuming a continuum distribution of electrolyte and catalyst even on the external surface of the cylinder there are active catalyst sites which can be reached by the reactant gas without the hindrances of any diffusion path in the electrolyte.

Formally this problem can be solved by introducing a thin film of pure electrolyte around the cylinder. The model converts them for very high i_0 to a Thin Film Model with the reaction localized on the surface of the cylinder, with diffusion through the thin film as the Thin Film Model, <u>but with ionic</u> current flowing mostly through the porous cylinder.

If the thickness of the thin film is δ and we now call C_0' the concentration of the reactant on the interface cylinder thin film to differentiate from C_0 solubility of gas, all the previous equations apply if C_0 is substituted by C_0' . In addition we will have the following relation between C_0 and C_0'

$$- \frac{dj(x)}{dx} = \frac{n F D (C_0 - C_0') 2 \pi r_0}{\delta}$$

A computer program with an additional equation could of course be easily written. The merit of this approach is doubtful, however, since δ is not known. This correction will be necessary when $C'_0 - C_0$ is large. According to the following equation

$$C_{o}' - C_{o} = \frac{1}{2 n \pi F \overline{D}} \left(\frac{\delta}{r_{o}}\right) \frac{d j (x)}{d x}$$

 $C_{o}' - C_{o}$ is large when $\left(\frac{\delta}{r_{o}}\right)$ is large and/or $\frac{d j(x)}{d x}$ is large (high $i_{o} \exp \frac{\alpha z F}{RT}$ η values).

For the oxygen electrode example treated above with $C_0 = 5.5 \times 10^{-8}$:

$$\frac{C_{o}'}{C_{o}} = 1 = \frac{4 \times 10^{5}}{\Theta} \times \left(\frac{\delta}{r_{o}}\right) \times \frac{d j (x)}{d x}$$

with $\frac{d j (x)}{d x}$ printed out by computer.

For $\theta = 0.5$:

Difference becomes significant

for $\frac{\delta}{r_0} = \frac{1}{10}$ when $\left|\frac{dj}{dx}\right| \sim 10^{-5}$ or for $\frac{\delta}{r_0} = \frac{1}{100}$ when $\left|\frac{dj}{dx}\right| \sim 10^{-4}$

The effect is not likely to be signifient for $r_0 = 10^{-5}$ cm may have an effect for $r_0 = 10^{-4}$ cm only if $i_0 = 10^{-6}$ and $\left(\frac{\delta}{r_0}\right) = \frac{1}{10}$.

For $\theta = 0.9$:

Effect should be significant only for $\frac{\delta}{r_0} = \frac{1}{10}$, $r_0 = 10^{-3}$, $i_0 = 10^{-6}$ and is not very significant for smaller $\frac{\delta}{r_0}$, r_0 or i_0 .

A more definite approach is of course to consider a noncontinuum dispersion of catalyst, conserving the rest of the assumptions. In this regard a physical understanding of the effect of agglomerate structure on tortuosity factor (both conductive and diffusive) would be very useful.

3. Constant Intrinsic Activity of the Catalyst Throughout the Cylinder

This assumption seems reasonable, although it is possible that under certain conditions a larger amount of bulk area is located in the core of the agglomerate. This could be handled mathematically by an expression relating γ to r_0 .

When large values of q exist (i.e. high values of i_0 , r_0 and η and/or low values of D and C_0), it may be advisable to form agglomerates with porous noncatalytic cores. This will result in significant savings of the catalyst.

4. Equilibration of Electrolyte Concentration in Cylinder Via Gas Phase

Due to the small diameter of cylinder compared with its length, this assumption seems more reasonable than the assumption (implicit in ref. 42) that concentration equalization occurs only via ionic migration in the axial direction of the flooded micropore system. * As a consequence of evaporation and condensation, electrolyte transport to the gas side of the oxygen electrode should be expected. A compensating counter flow of electrolyte from the gas side to the electrolyte side can be expected also. Indeed, the often observed "weeping" of oxygen electrodes could be explained at least partially by this mechanism.

* This is independent of the fact that our assumptions greatly simplify the mathematical treatment.

5. Direct Relationship Between Local Current and Local Concentration of Reactant

Modification of this assumption does not change the model basically. If needed, another concentration dependence can be used, but the mathematics will be considerably different since the differential equation (3) will cease to be linear.

6. No Radial Voltage Drop and Axial Concentration Difference

These assumptions seem reasonable since h is very large compared with ${\bf r}_{\rm O}$.

7. No Transport Limitation in the Gas Phase

Transport limitations should be small in the case of thin electrodes $(h \sim 0.2 \text{ mm})$, high O_2 -pressures ($P_{O_2} > 0.75 \text{ atm}$), moderate currents $(i < 200 \text{ ma/cm}^2)$, and high gas porosity. If these conditions are exceeded, gas diffusion hindrances have to be considered. Such a consideration could be done with relative ease since the assumption is not essential to the model.

Consideration of gas diffusion hindrances in our model is indeed advisable when trying to optimize structures for high current drains. Experimentally, the effect of O_2 -partial pressure should be studied.

8. The Process of Gas Dissolution is Not Kinetically Limited

This assumption seems reasonable. Kinetic expression for solubility could be considered in the treatment of the model but does not seem necessary.

9. No Electronic iR Drop in Cylinder

Such an assumption seems reasonable; however, it should be tested when trying to optimize electrodes for high current drains.

10. Absence of Convection

Convection has been found to occur in free menisci⁽³⁴⁾; it seems unlikely that it occurs at an appreciable degree inside of a porous agglomerate.

11. All Cylinders Have the Same Radius

This assumption is to some extent justified by the high degree of lateral interlocking of the agglomerates. The effect of varying the radius

- 220 -

of agglomerates in translating the results of a cylinder to the electrode should however be investigated in subsequent work.

III. APPENDIX

A. NOTES ON THE PROGRAM

The basic problem to be solved numerically is that of integrating the nondimensional equation

$$\frac{\mathrm{d}^2 \eta'}{\mathrm{dx'}^2} = \frac{2\mathrm{nF}\,\bar{\mathrm{D}}\,\mathrm{C_0h}^2}{\eta_0\bar{\kappa}\mathrm{r_0}^2} \left[1 - \exp\left(-\frac{z\eta_0}{\phi} \cdot \eta'\right)\right] - \frac{\mathrm{q}\,\mathrm{I_1(q)}}{\mathrm{I_0(q)}}$$

where
$$q = \left(\frac{\gamma i_{o} r_{o}^{2}}{n F \overline{D} C_{o}}\right)^{\overline{2}} \exp \left\{ \left(\frac{\alpha Z \eta_{o}}{2\phi}\right) \eta' \right\}$$

subject to the boundary conditions

$$\eta' = 1$$
 at $x' = 0$,
 $\frac{d\eta'}{dx'} = 0$ at $x' = 1$.

The solution is required in the range o $\leq x' \leq 1$, and so we have a nonlinear equation with 2 point boundary conditions. Such an equation has to be solved iteratively.

The method used is the " η " method described in L. Fox, Numerical Solution of Two-point Boundary Problems in Ordinary Differential Equations. Oxford University Press, 1957, p. 87.

Our equation is basically of the form

CONTRACTOR OF THE

$$\frac{d^2y}{dx^2} = f(y) \qquad \text{where } y = \eta', x = x' \text{ and } f \text{ is defined}$$

suitably.

Suppose Y(x) is an approximate solution. Suppose z(x) describes the error in this solution. Then y = Y + z is the true solution. Substitute this in the governing equation

$$\frac{d^2 z}{dx^2} - \left[\frac{\partial f}{\partial y}\right]_{y=Y} z = f(Y) - \frac{d^2 Y}{dx^2}$$

if we neglect all but the first order terms in z. This is a linear equation for z. Given Y, z can be calculated from this equation and then Y + z is the improved solution. The iteration can be repeated as often as required.

Difference Scheme

The range 0 to 1 is subdivided in intervals of 1/20N by tabular points, where N is an integer that can be varied

They are numbered as shown. One point beyond the physical range at x' = 1 + 1/20N is taken so as to accommodate the zero derivative boundary condition at x' = 1.

At the I' th point of the range for I = 2 to (20N + 1) the differential equation is approximated by the difference equation

$$(1 - \frac{1}{12}h^{2}f'(Y_{I+1}))z_{I+1} + (-2 - \frac{5}{6}h^{2}f'(Y_{I}))z_{I} + (1 - \frac{1}{12}h^{2}f'(Y_{I-1}))z_{I-1}$$
$$= \frac{1}{12}h^{2}f(Y_{I+1}) + \frac{5}{6}h^{2}f(Y_{I}) + \frac{1}{12}h^{2}f(Y_{I-1}) - Y_{I+1} + 2Y_{I} - Y_{I-1}$$

- 227 -

where the subscripts refer to the points where variables are evaluated. Here the prime refers to the derivative and h = 1/(20 N) is the step length. The above is well known to be the most accurate 3-point difference scheme possible. The error is of the order of h^6 . (Fox, p. 68)

The initial approximate solution is taken as $Y = (1 - x)^2$, which satisfies both boundary conditions. Thereafter we solve the above difference equation for z, and ensure that the boundary conditions are satisfied by making

 $z_1 = 0, z_{20N+2} = z_{20N}$

Note that, because of the simple form of one problem, the solution must be symmetric about x' = 1 so that the second requirement here ensures that the boundary condition of vanishing first derivative at x' = 1 is satisfied with the same degree of accuracy as the rest of our difference scheme.

The method described above converges rapidly. Currently, the iteration is continued until the correction z is less than 10^{-5} at all points, though this could be changed by just altering the number in the order

1F (XM - 0.00001) 34, 34, 37.

The input must be of the following form

Card 1: α, z, C_0, ϕ FORMAT (7E 10.4)Card 2: κ, D, η_0, h (length of cylinder)"Card 3:4 integers in FORMAT (4I3)(1)N for number (20N + 2) of integration points. ($2 \le N \le 25$)(2)Number of values of θ to be used.(3)Number of values of r_0 to be used.

(4) Number of values of i_0 to be used.

| Card 4: | Values of θ | FORMAT (7E 10.4) |
|---------|--------------------------|------------------|
| Card 5: | Values of r _o | 11 |
| Card 6: | Values of i _o | ** |

More than one card can be used for values of θ , r_0 , i_0 as needed. These sets of cards may be repeated.

Program can be stopped by ending with a card 1 with $\alpha < 0$.
