ABSTRACT

The elements F, Cl, Ni, Co, Cu, Ga, Sc, Cr, V, Ba and Sr have been determined in two drill cores through a differentiated tholeiitic dolerite sill from Tasmania. A multivariate statistical technique is employed to demonstrate the occupancy of hydroxyl lattice sites by both chlorine and fluorine. Consideration of trace-element/major element ratios suggests that, in these dolerites, Ni occupies Fe^{+2} sites, Co and Sc replace both Mg and Fe^{+2}, Cr replaces Fe^{+3}, V^{+4} replaces Ti, Ga replaces Al, and Ba and Sr both replace Ca.

INTRODUCTION

Tholeiitic dolerites of Jurassic age are of widespread occurrence in Tasmania. Edwards (1942) has shown that these dolerites are commonly differentiated and are similar in composition to those of the Karoo, Palisades and Antarctica provinces. The effect of the limited differentiation of the Mt. Wellington sheet on the distribution of major and trace elements has been studied by Edwards (1942) and Tiller (1959); in the Red Hill intrusion, differentiation has produced silicic granophyre and this body has been studied in detail by McDougall (1962) and the variation of Ni, Co, Cr and Cu reported by McDougall and Lovering (1963).

The structure of the Great Lake sheet has been discussed by Carey (1958) and McDougall (1964). Numerous bore holes have been drilled through this sheet and the physical and petrological properties of some of these cores studied by Jaeger and Joplin (1955), Joplin and Jaeger (1957), Jaeger and Green (1958), and McDougall (1958). McDougall (1964) has recently completed a detailed study of the petrology and major element composition of two cores from this sheet and shown that one, D.D.H. 5084, is very similar to the Mt. Wellington sheet, and the other, D.D.H. 5123, is markedly more differentiated in that granophyre has been produced in the upper 70-100 feet. These two cores, then, exhibit the complete range of fractionation found in the Tasmanian dolerites.

Although several studies of trace element variation during magmatic differentiation have been reported previously (e.g. Wager and Mitchell, 1951; Nockolds and Allen, 1956; McDougall and Lovering, 1963) the behaviour of fluorine and chlorine has not previously been examined. In view of the advantages associated with the study of bore hole material and the extensive physical, chemical and mineralogical data already available from the Great Lake dolerite sheet, an investigation of the trace element distribution in the same samples studied by McDougall should prove of fundamental importance to our understanding of the differentiation of tholeiitic magmas.

Description of the Great Lake Dolerite Sheet

The Great Lake dolerite is a large transgressive sheet of Jurassic age. Adjacent to Great Lake it is of the order of 2000 feet thick and granophyre, of very limited lateral extent, has been produced only in this area. The 5123 bore hole commenced in granophyre and grades downward into acid dolerite at a depth of 70-100 feet. Eastwards, the sheet rises steeply

and in the region of the Tiers Arch (Carey, 1958) becomes only 100-200 feet thick; further eastwards it again achieves a thickness in excess of 1200 feet. The 5084 core is from this region of the sheet. The paper by McDougall (1964) provides block diagrams illustrating the structure of the sheet and the location of the bore holes.

Modal analyses of 5123 and 5084 have been reported by McDougall (1958; 1964). The lower zone dolerites consist of approximately 45% clinopyroxene, 40% plagioclase, up to 8% orthopyroxene, 2% iron ore, with the residue being made up by a poorly crystallized mesostassis. In the central zone dolerites, orthopyroxene disappears and the proportion of clino-pyroxene steadily decreases; plagioclase and iron ore increase slightly and mesostasis increases markedly. Granophyre, found only in 5123, is formed by a rapid increase in mesostasis at the expense of the other constituents.

The pyroxene of the lower and central zone dolerites consists of equal proportions of augite and pigeonite; the plagioclase of both regions is labradorite commonly zoned to a rim of andesine. An intergrowth of quartz and alkali feldspar is rarely visible in the mesostasis of the lower zone but is somewhat more common in the central zone dolerites. Microlites of pyroxene and needles of apatite are also observed in the mesostatis of the central zone. In the granophyre, the plagioclase remains labradorite but pigeonite is absent and the pyroxene is ferroaugite.

ANALYTICAL METHODS

The analytical procedures for chlorine and fluorine have been described in detail elsewhere (Greenland and Lovering, 1964a). In brief, chlorine was determined by fusion of the powdered rock sample in an Edwards-

Urey type distillation device (Edwards and Urey, 1955) and analysis of the

distillate by a micro-diffusion technique as described by Conway (1957);

fluorine was determined by an emission spectrographic technique employing

the CaF emission bands and the CaO bands as internal standard. In both

cases, precision is approximately $\pm 10\%$ of the amount present as estimated

from numerous replicate analyses of a single sample.

The emission spectrographic procedure employed in the determina-

tion of Ni, Co, Cu, Ga, Sc, Cr, V, Sr, and Ba has also been described pre-

viously (Greenland and Lovering, 1964b). Samples were mixed 1:1 with

graphite containing palladium as internal standard and arced in duplicate

in an oxygen stream. Dilutions of the U.S.G.S. standard diabase W-1 were

used as standards. The analytical precision was estimated from 14 single

arcings of a dolerite scattered throughout the samples studied here; these

results are shown in Table 1 expressed as a relative error.

RESULTS

The analytical results of the 5123 drill core are presented in

Table 2 and of the 5084 core in Table 3. Ratios of the trace elements to

certain major elements have been computed from the data of McDougall (1964)

and are shown in Table 4.

It is convenient to have an index of differentiation in order to

combine the data from the two bore holes. McDougall (1964) has shown that

differentiation in the Great Lake sheet was controlled by fractionation in

the pyroxene series and thus the mafic index, $\frac{(Fe^{+2} + Fe^{+3}) \times 100}{Fe^{+2} + Fe^{+3} + Mg}$, of Wager

and Deer (1939) and Simpson (1954) provides a satisfactory measure of the

degree of fractionation. This ratio has been computed by McDougall (1964)

for these samples and has been included in Tables 2, 3, and 4. The combined

data of these two cores have then been plotted against this index in Figures

1, 2, and 3 thus illustrating the fractionation patterns of the trace elements with differentiation; since the analytical error of the determinations is log-normally distributed, a logarithmic concentration scale has been employed.

The ionic radii and electronegativities of a number of elements have been assembled in Table 5 since these properties are generally believed to govern their fractionation during crystallization differentiation and are frequently referred to in the text.

Fluorine:

Correns (1956) has reviewed the geochemistry of fluorine and concluded that there appears to be no correlation between fluorine content and chemical composition of a rock. No study of the variation of fluorine during differentiation of a basic magma has been published and, while Correns' conclusion may be generally true, fluorine would be expected to become enriched in the most acid fraction of a differentiated sequence. According to Correns (1956), fluorine may occur as independent minerals (apatite, fluorite) or may replace hydroxyl ions in micas and amphiboles. Of these minerals, only apatite has been detected in thin sections from these cores (McDougall, 1964) and thus fluorine is presumably concentrated in the mphostassis.

In 5123, fluorine is reasonably constant in the lower zone dolerites and increases steadily through the central zone to a maximum in the granophyres. The lower zone dolerites of 5084 are also depleted in fluorine relative to the central zone and it is apparent that crystal fractionation of the Great Lake sheet has led to enrichment of the residual magma in fluorine. Figure 1 shows that fluorine is enriched to about the same degree as barium and gallium in the final crystallates of the magma. In fact, the profile of fluorine with depth is very similar to that of barium in both cores demonstrating that

similar distributions do not necessarily imply identical lattice sites.

Although apatite is universally present in the mesostassis of these rocks, there is insufficient phosphorus to account for even half the fluorine as a pure fluor-apatite. Evidence that fluorine is replacing hydroxyl ions is presented in a later section.

Chlorine:

The distribution of chlorine through a differentiated sequence has not been described previously, but Correns (1956) has concluded that there is no general enrichment of chlorine in acid rocks relative to basic rocks. In silicate rocks, chlorine occurs predominantly in micas and hornblendes, replacing the hydroxyl ion, but may also be present as solutions in mineral inclusions or dissolved in rock glass (Correns, 1956), and thus is expected to be concentrated in the mesostassis of the Great Lake sheet.

The fractionation of chlorine in 5123 is considerably less marked than that of fluorine though the slight enrichment of chlorine in the central zone dolerites and granophyres does parallel the enrichment of fluorine. Although slightly enriched in the earliest central zone dolerites of 5084, the degree of fractionation is much less than that of fluorine or even of chlorine itself in 5123. The variation of chlorine with differentiation is shown in Figure 1 which confirms the very slight fractionation of chlorine particularly as compared with fluorine. This is a surprising result since the larger ionic radius of chlorine and its well known ability to form complex molecules should lead to greater concentration of chlorine than fluorine in residual magmas; these facts, as well as the water solubility of chlorine compounds, have been advanced as an explanation for the high

Cl/F ratio obtaining in volcanic gases (Correns, 1956). The most likely explanation of this anomalous distribution is that volatiles have been lost from the magma chamber during crystallization and it is of interest, therefore, that McDougall (1964) has been led to invoke a loss of volatiles through joints in the overlying dolerites and sediments on independent grounds. The chilled contact of 5084 gives no reliable evidence on this point since it is actually _depleted_ in chlorine relative to the bulk of both cores, and, if taken as representative of the original content of chlorine in the magma, would require the addition of chlorine during crystallization; this sample contains evidence of a subsequent alteration (McDougall, personal communication) and it is probable that chlorine was lost at this time.

Nickel:

Vogt (1923) presented extensive evidence that nickel is camouflaged by magnesium and this view has subsequently been supported by more recent authors (Wager and Mitchell, 1951; Goldschmidt, 1954). Ringwood (1955a, 1956) suggests, however, that due to similar ionic radii and electronegativities, the nickel-iron diadochy should be of paramount importance, and support for this conclusion is derived from the high abundance of nickel in iron oxides, (Wilkinson, 1959; McDougall and Lovering, 1963). On the other hand, Snyder (1959) has criticized Ringwood's discussion and favours the nickel-magnesium diadochy as the more important. In the Tasmanian dolerites at Mt. Wellington and Red Hill, the iron ore contains approximately twice as much nickel as do co-existing pyroxenes (Tiller, 1959; McDougall and Lovering, 1963) and thus the $Ni-Fe^{+2}$ diadochy might be expected to be of most importance in the Great Lake sheet.

However electron probe studies (Lovering, unpublished work) have shown that magnetite grains in some eclogitic rocks contain very small ($\sim 1\mu$) sulphide blebs. Semiquantitative analyses using the electron probe indicate that these sulphide blebs are composed of chalcopyrite, various iron sulphides and an iron-nickel-cobalt sulphide of some type. It is not impossible that similar sulphide blebs could occur in the iron ores extracted from the Tasmanian dolerites so that the nickel (and cobalt) found in these iron ores may occur in a separate sulphide phase.

In 5123, nickel is uniformly abundant at about 115 p.p.m. at depths greater than 1000' and declines smoothly from this point to 5.5 p.p.m. Ni in the uppermost central zone dolerites; the granophyres contain nickel below the detection limit of 2 p.p.m. Ni. In 5084 nickel shows a pronounced peak in the most basic portion (200'-300') of the core and declines steadily through the central zone dolerites. The profile of nickel through both cores is very similar to that of magnesium, as has also been noted in the Mt. Wellington sill (Tiller, 1959). This is not necessarily evidence for Ni-Mg diadochy, however, since chromium also possesses a very similar profile although it is known to be replacing ferric iron.

Figure 3 shows the smooth decrease of nickel with differentiation. Nickel and chromium are the trace elements most severely affected by fractional crystallization in the Great Lake sheet, as has been found in other differentiated dolerites (Nockolds and Allen, 1956), but they differ from each other in that the decrease of chromium is more rapid than of nickel and nickel is not enriched in the final differentiates as is chromium.

If nickel is replacing magnesium, the Ni/Mg ratio should increase during differentiation whereas if it is replacing iron the Ni/Fe^{+2} ratio should decrease since the ionic radius and electronegativity of nickel is intermediate between that of magnesium and iron. In fact, both ratios decrease which strongly suggests that the fractionation of nickel has proceeded independently of that of magnesium. This is in accord with the smooth curve obtained from a plot of Ni/FeO against an index of differentiation in contrast to the scatter of Ni/MgO points (Figure 4). Thus it seems probable that at least in the Tasmanian dolerites the $Ni-Fe^{+2}$ diadochy is of greater importance than that of Ni-Mg in agreement with Ringwood's (1955a) interpretation.

Scandium and Cobalt:

These elements are alike in their ability to replace magnesium and di-valent iron and commonly show similar fractionation patterns during igneous differentiation (Wager and Mitchell, 1951; Nockolds and Allen, 1956). Tiller (1959) and McDougall and Lovering (1963) have shown that the iron ore* contains more cobalt than do co-existing pyroxenes in the Tasmanian dolerites but since iron ore constitutes less than 5% of the total rock (McDougall, 1964) the variation of cobalt must be attributed primarily to the pyroxenes.

Both cobalt and scandium increase from the bottom of 5123 to a slight maximum in the 1200'-700' portion of the core and then slowly decrease till the appearance of granophyre when they fall abruptly. In 5084 they again parallel each other by rising slightly from the chilled contact values to form maxima in the 200'-300' portion of the core, rise to further maxima

* Co may occur in separate sulphide phases included in the iron ores (see Nickel discussion).

in the uppermost lower zone dolerites and gradually decrease through the
central zone. The trend of both scandium and cobalt through these cores
is very similar to that of magnesium suggesting that they may be replacing
Mg rather than iron in the pyroxenes. On the other hand, a similarity of
profiles of the two elements does not necessarily imply that their lattice
sites are identical.

The abundance of scandium and cobalt decrease with differentiation
but the rate of change in the more acid differentiates appears to be some-
what greater for scandium. A similar distribution for these elements has
been shown to hold for a large number of differentiated tholeiitic magmas
by Nockolds and Allen (1956). The Co/Mg and Sc/Mg ratios increase rapidly
while the Co/Fe^{+2} and Sc/Fe^{+2} ratios decrease with differentiation. These
ratios correspond to the result to be expected from consideration of the
relevant ionic radii and electronegativities (Table 5). The ratios of
cobalt and scandium with magnesium adhere somewhat more closely to a smooth
curve when plotted against an index of differentiation than do their ratios
with iron (Figures 5 and 6), again suggesting that they are more closely
associated with magnesium than with iron.

Copper:

Copper replaces sodium and di-valent iron in silicate and oxide
minerals as well as forming independent sulphide minerals (Wager and Mitchell,
1951; Snyder, 1959). In the Mt. Wellington dolerite of Tasmania, Tiller
(1959) has shown that copper is present in the pyroxene, plagioclase and
iron ore fractions and McDougall and Lovering (1963) have demonstrated the
same distribution of copper in the Red Hill (Tasmania) granophyre; it therefore

seems probable that the Great Lake sheet also contains a distribution of copper between the silicate, oxide and sulphide minerals.

In 5123 copper is low (35-50 p.p.m.) in the lower zone dolerites, rises to a maximum of 100-150 p.p.m. in the central zone and abruptly decreases in the granophyres to 44 p.p.m. In 5084 it is depleted in the lower zone and rises to a maximum in the central zone dolerites. The distribution of copper in 5084 is very similar to that found by Tiller (1959) for the Mt. Wellington sill, whereas the distribution in 5123 parallels that found at Red Hill (McDougall and Lovering, 1963) and in the Skaergaard intrusion (Wager and Mitchell, 1951).

The rapid increase in copper content with differentiation to a maximum at a mafic index of 70-80 followed by an abrupt decline is shown clearly in Figure 2. The peak in copper abundance preceding the appearance of granophyre has been attributed to the separation of an immiscible sulphide phase (Wager and Mitchell, 1951; McDougall and Lovering, 1963) and appears to be a general accompaniment to magmatic fractional crystallization.

Gallium:

Gallium is commonly camouflaged by tri-valent iron and aluminium during magmatic differentiation and occurs predominantly in the feldspars and magnetite (Shaw, 1957). In the Great Lake sheet, magnetite is present at 5% while plagioclase constitutes 40-50% of the rock (McDougall, 1964) and thus the feldspar would be expected to account for virtually all of the gallium.

Gallium decreases with depth through nearly the entire length of 5123; it falls rapidly from 33 p.p.m. Ga at 10' to 19 p.p.m. Ga at 200' and decreases more slowly to 6.2 p.p.m. Ga at 1400', after which it begins to rise

again. In 5084, the gallium content decreases from the chilled contact value of 13 p.p.m. Ga to a minimum of 8.5 p.p.m. Ga at a height of 195' after which it increases to a maximum of 20 p.p.m. Ga in the upper part of the core. It is apparent that gallium was greatly concentrated in the residual magma during crystallization differentiation and, in fact, the degree of gallium fractionation in 5123 very closely approximates that of the Skaergaard intrusion; in the latter, Wager and Mitchell (1951) record a range of 8 to 35 p.p.m. Ga in rocks originating from a parent magma containing 17 p.p.m. Ga.

When the data from both drill cores are combined and plotted against an index of differentiation, it may be seen that gallium increases linearly with differentiation (Figure 1). The Ga/Al (Table 4) ratio also increases with differentiation as is common in tholeiitic magmas (Wager and Mitchell, 1951; Nockolds and Allen, 1956) and probably reflects the greater radius and electronegativity of gallium with respect to aluminium.

Chromium:

Chromium is camouflaged by ferric iron in magnetite and pyroxenes and may form an independent chrome-spinel mineral at concentrations as low as 250 p.p.m. Cr in the magma (Wager and Mitchell, 1951). McDougall and Lovering (1963) have shown that in the Red Hill dolerite, the iron ore contains more chromium than does co-existing pyroxene but the total rock contains almost twice as much chromium as can be accounted for by the pyroxenes and iron ore; they were unable to decide whether this reflected an analytical bias or the presence of chromite. Nevertheless, the preponderance of pyroxene in the Great Lake sheet (McDougall, 1964) indicates that the variation of chromium in the rock is predominantly due to the pyroxenes.

The chromium content of 5123 falls rapidly from the high abundance in the deepest portion of the core to a plateau of approximately 10 p.p.m. Cr in the central zone dolerites and is absent ($<$2 p.p.m.) from the final granophyre at a depth of 10'. In 5084, chromium is greatly enriched in the most basic part of the core (100'-300') and declines steadily through the central zone dolerites. The extreme fractionation of chromium invariably attends magmatic differentiation (Nockolds and Mitchell, 1946; Wager and Mitchell, 1951; Nockolds and Allen, 1956) and is usually attributed to the smaller size and electronegativity of the Cr^{+3} ion relative to Fe^{+3} leading to enrichment of the early crystals in chromium and consequent rapid depletion of the magma.

The rapid decrease of chromium with differentiation is clearly shown in Figure 3 which also indicates a slight increase of chromium in the final differentiates. The final enrichment of chromium has been attributed to a change in oxidation state (Wager and Mitchell, 1951) and to the formation of a complex (Ringwood, 1955b). The change in properties of chromium is also shown by the Cr/Fe^{+3} ratio (Table 4) which decreases sharply at first but remains essentially constant in the later differentiates.

Vanadium:

Vanadium is usually concentrated in the iron ore fraction of silicate rocks in which it replaces titanium and iron and, to a lesser extent, in the pyroxenes replacing tri-valent iron. Tiller (1959) has shown that in the Mt. Wellington sill (Tasmania) the ore contains 3-4 times as much vanadium as do co-existing pyroxenes and a similar distribution can be expected for the Great Lake sheet.

Vanadium is remarkably constant in the dolerites of 5123, showing only a slight maximum in the 800'-900' portion, and decreases abruptly in the granophyres. It is more variable in 5084 in that it is slightly enriched in the most basic 200'-300' portion of the core and declines in the central zone dolerites. Tiller (1959) has described a similar distribution in the Mt. Wellington dolerites. The uniform abundance of vanadium in the Tasmanian dolerites is in marked contrast to the strong fractionation exhibited in the Skaergaard (Wager and Mitchell, 1951), Dillsburg (Hotz, 1953), and most other differentiated tholeiites (Nockolds and Allen, 1956), and probably reflects the very minor and rather constant amount of ore obtaining in the Great Lake dolerites.

In accord with this distribution, vanadium changes little with differentiation until the abrupt decrease in the granophyre (Figure 2). The great impoverishment of the granophyre in vanadium is due to the steady depletion of the magma since most of the 5123 core contains slightly more vanadium than the original magma as represented by the chilled margin of 5084. The ionic radius and electronegativity of quadri-valent vanadium is less than that of ferric iron and thus the V/Fe^{+3} ratio is expected to decrease during differentiation and this is found to be true of these rocks. The V/Ti ratio is also expected to decrease during differentiation due to the smaller radius of V^{+4} and the observation that this ratio adheres more closely to a smooth curve with differentiation than does the V/Fe^{+3} ratio (Figure 7) suggests that vanadium is more closely associated with titanium than with ferric iron in the Great Lake sheet.

Barium:

The ionic radius of barium is such that it may be camouflaged by calcium or captured by potassium bearing minerals and its fractionation

during differentiation is generally very similar to that of potassium

(Wager and Mitchell, 1951; Nockolds and Allen, 1956; Þotz, 1953).

The barium content of 5123 decreases rapidly with depth from 550 p.p.m. at 50' to 120 p.p.m. at 1200' after which it remains essentially constant. In 5084, it falls abruptly from the chilled contact value of 500 p.p.m. to 200 p.p.m. and begins a gradual rise at the 250' height. If the chilled contact of 5084 is taken as representative of the composition of the original magma, it is apparent that barium must have been lost during crystallization since only the granophyres of 5123 contain as much barium as the original abundance. McDougall (personal communication) considers the 5084 contact to be slightly altered, however, and it may be that barium has been added to this sample during the alteration.

The great enrichment of the residual magma in barium is clearly shown in Figure 1 where the combined data are plotted against an index of differentiation. The fractionation of barium is similar to that of potassium in these cores but this does not necessarily indicate their occupation of identical lattice sites. The Ba/K ratio is highly variable and shows no discernible trend with differentiation whereas the Ba/Ca ratio defines a smooth curve increasing with differentiation (Figure 8). This strongly suggests that the barium is present in the plagioclase and therefore varies independently of potassium. The increase of the Ba/Ca ratio may be attributed to the greater radius of barium which causes its preferential exclusion from the early crystallates.

Strontium:

The strontium-calcium diadochy is well known and results in the concentration of strontium in the plagioclase fraction of a rock (Nockolds and Mitchell, 1945; Wager and Mitchell, 1951).

The strontium content of the Great Lake sheet has been only slightly affected by differentiation. Strontium falls from 190 p.p.m. in the granophyre of 5123 to a minimum of 98 p.p.m. in the lower zone dolerites; in 5084 it falls from the chilled contact value of 150 p.p.m. to 100 p.p.m. Sr in the most basic rock before rising slowly to a maximum of 170 p.p.m. in the central zone dolerites. In the Skaergaard intrusion, strontium rises to a maximum before decreasing in the granophyre fraction (Wager and Mitchell, 1951) and the same pattern has been found for the differentiated dolerite of Dillsburg (Hotz, 1953), but if such a maximum is present in the Great Lake sheet it is too small to detect.

The increase of strontium with differentiation is shown in Figure 1 to be curvilinear with the greatest rate of change at low mafic index values; again there is no indication of a maximum preceding the granophyre stage. The Sr/Ca ratio (Table 4) also increases with differentiation and the increase is most rapid in the final differentiates. This may be attributed to the larger size of the strontium ion and is invariably found in differentiated sequences (Nockolds and Mitchell, 1946; Wager and Mitchell, 1951; Nockolds and Allen, 1956).

DISCUSSION

Comparison of the Great Lake Magma with Other Tholeiitic Basalts.
The chilled margin of an intrusion is generally accepted as an approximation to the composition of the original magma. Table 6 compares trace element concentrations of the lower contact of 5084 with similar samples from other tholeiitic basalts and with the "average basalt" of Turekian and Wedepohl (1961).

Unfortunately, McDougall (personal communication) has found evidence of a slight hydro-thermal alteration in this sample and thus the value of such a comparison may be somewhat dubious; in fact, comparison of these results with the distribution found in the two cores strongly suggests that barium has been added and chlorine lost from this sample. Nevertheless, Table 6 indicates the general similarity of the assumed Great Lake magma to other Tasmanian magmas (in so far as comparison is possible) that might be expected. It contains considerably less Ni, Co, Cr and Cu than do the Hawaiian, Karroo and Skaergaard dolerites and rather more Sc. Except for the depletion of strontium, the Great Lake sheet compares remarkably closely with the average basalt.

Lattice Sites Occupied by Fluorine and Chlorine. Since the behaviour of the halogens during differentiation has not previously been studied, it is of some interest to determine their mode of occurrence in the Great Lake sheet. Fluorine and chlorine normally occur in apatite at hydroxyl lattice sites; fluorine can also form fluorite or replace oxygen while chlorine can occur independently in sodalite and scapolite. It has been noted previously that there is insufficient phosphorus in the Great Lake sheet to account for either of the halogens as apatite and thus if it can be shown that fluorine and chlorine are occupying identical lattice sites they must be replacing the hydroxyl ion. Examination of thin sections has failed to detect any of the independent fluorine and chlorine minerals (McDougall, personal communication) but this is not conclusive and a multi-variate statistical technique will be employed to show that chlorine and fluorine do in fact occur in the same lattice site.

It has been stressed previously that similar concentration trends of two elements with depth or index of differentiation does not necessarily imply an identity of lattice sites. It is therefore necessary to consider the residual variations after removal of the effects produced by differentiation. To do this, we assume that the observed abundance Z_i', ($Z_1 =$ log Cl, $Z_2 =$ log F) at any depth D in the core is the sum of three independent functions: the depth of the sample; the availability of lattice sites, S_i'; and the analytical error of the determination, γ_i'. Therefore Z_i' $f(D_i') + h(S_i') + g(\gamma_i')$. It is obvious that $f(D_i')$ and $h(S_i')$ are not actually independent functions but $h(S_i')$ may be considered as random variations of lattice sites whereas $f(D_i')$ may be attributed to the smooth variation with differentiation. Thus we further assume that $f(D_i')$ is a simple, smooth curve and that the observed scatter of the data represents irregularities of crystallization from the magma and analytical error. The removal of the effect of $f(D_i')$ on Z_i' then yields two new functions: $Z_i' = g(\gamma_i') + h(S_i')$.

Fluorine and chlorine were determined independently of each other and thus the analytical errors of the determinations cannot be correlated, implying that $g(\gamma_1')$ and $g(\gamma_2')$ are completely independent functions. Therefore, any relationship found between Z_1' and Z_2' must reflect a relationship between $h(S_1)$ and $h(S_2)$ implying that the small scale variations of fluorine and chlorine lattice sites are identical, which in turn suggests that the sites are in fact identical.

The first problem then, is the computation of $f(D_i')$. Observation of the profiles of fluorine and chlorine with depth in 5123 (Figure 9) suggests that the general trend of the data may be satisfactorily approximated with a parabola. With this assumption, $f(D_i')$ may be computed by standard least square methods (Ezekial and Fox, 1959). It should be noted that the abundance values

have been transformed to their logarithms in order to satisfy the statistical
requirement of homocedacity since it is known from experimental considerations
that the analytical error of both determinations is distributed approximately
log-normally. The curves finally arrived at are:

$$\log F = 2.814 - 6.3208 \times 10^{-4}D + 2.3875 \times 10^{-7}D^2$$

$$\log Cl = 2.0605 - 5.4648 \times 10^{-4}D + 3.0254 \times 10^{-7}D^2$$

These are shown plotted with the observed Z_λ in Figure 9. From
these parabolas a "calculated" abundance of the halogens may be obtained at
any depth which, when subtracted from the "observed" abundance, yields the
Z'_λ values.

Given these values of Z_λ', a least squares straight line of the
form $Z_\lambda' = A + BZ'_2$ may be fitted to these data. This has been done by
standard techniques to yield:

$$(\log F)' = 0.0039 + 1.0015 \ (\log Cl)'$$

The correlation coefficient computed from these data indicates a
highly significant relationship between the Z'_λ functions and thus, in view
of the preceding discussion, the inference that fluorine and chlorine are
occupying identical lattice sites appears to be warranted. The coefficients
of this equation are of some interest. The computed value of A does not differ
significantly from zero which indicates that when no chlorine sites are avail-
able, there are no fluorine sites; the coefficient B does not differ signifi-
cantly from one indicating that an increase of chlorine sites yields an equal
increase of fluorine sites. Thus both coefficients agree in the implication
of an identity of fluorine and chlorine lattice sites. Although no hydroxyl
minerals have been observed in thin section, it appears probable therefore
that they do exist as sub-microscopic inclusions in the mesostassis and that

they do contain most of the fluorine and chlorine present in the Great Lake dolerite.

Small Scale Variation in the Cores. McDougall (1964) has noted the presence of a finer scale variation in the Great Lake dolerites and specifically cites the abnormally low MgO content of the 900' sample of 5123. To further determine the extent of this "ripple", samples from 890' and 950' were also included in the trace element study. The 900' sample contains less Cr, Sc, V, Ni and Co and more Ga, Sr, F and Cl than either the 890' or 950' samples confirming the irregular variation in this region of the core. From the profiles there appears to be a rather gradual increase of "acidity" from 1000'-900', an abrupt decrease between 900'-890', followed by the gradual increase through the central zone dolerites. Thus, the variation is limited to 100' and may be considerably less. Small scale variations such as this are probably of frequent occurrence in these dolerites and a more detailed study of them than was possible here might be of considerable interest.

CONCLUSION

The general fractionation of trace elements in the Great Lake dolerites is similar to those found in most differentiated basic tholeiitic magmas. Nickel and chromium become greatly depleted and cobalt and scandium slightly depleted in the residual magmas. Vanadium decreases only slightly with differentiation but is virtually exhausted by the granophyre stage. Copper rises rapidly with differentiation to a maximum and is then removed, presumably by separation of an immiscible sulphide phase. Strontium increases slightly and fluorine, barium and gallium increase greatly with differentiation. Chlorine may increase slightly in these dolerites but it appears probable that chlorine has been lost with other volatiles during crystallization

of the Great Lake sheet.

In these dolerites, it is believed that Ni occupies Fe^{+2} sites, Co and Sc replace both Mg and Fe^{+2}; Cr replaces Fe^{+3} until the later stages when a change of oxidation state probably occurs; V^{+4} replaces Ti^{+4}; Ba and Sr replace Ca in the plagioclase; Ca replaces Al, while F and Cl occupy hydroxyl sites in the poorly crystallized material of the mesostassis.

A: Great Lake Sheet, Chilled Contact of 5084.
B: Red Hill, McDougall and Lovering, 1963 (F determined here).
C: Mt. Wellington, Tiller, 1959.
D: Hawaiian Tholeiitic Basalts)
E: Karroo Dolerites)
F: British Tertiary Tholeiitic) Nockolds and Allen, 1956.
G: Nakone Volcanics)
H: Northfield Sill)
I: Dillsberg Dolerite, Notz, 1953.
J: Skaergaard, Wager and Mitchell, 1951.
K: Average Basalt, Turekian and Wedepohl, 1961.

FIGURE CAPTIONS

Figure 1. Variation of F, Cl, Ga, Ba, and Sr with differentiation in the Great Lake sheet.

Figure 2. Variation of Cu, V, Co, and Sc with differentiation in the Great Lake sheet.

Figure 3. Variation of Ni and Cr with differentiation in the Great Lake sheet.

Figure 4. Variation of the Ni/FeO and Ni/MgO ratios with differentiation in the Great Lake sheet.

Figure 5. Variation of the Co/FeO and $\overset{Co}{\cancel{Se}}$/MgO ratios with differentiation in the Great Lake sheet.

Figure 6. Variation of the Sc/FeO and Sc/MgO ratios with differentiation in the Great Lake sheet.

Figure 7. Variation of the V/Fe_2O_3 and V/TiO_2 ratios with differentiation in the Great Lake sheet.

Figure 8. Variation of the Ba/K_2O and Ba/CaO ratios with differentiation in the Great Lake sheet.

Figure 9. Variation of F and Cl with depth in the D.D.H. 5123 core showing the least-squares fitted parabolas.
