The Relative Utility Hypothesis With and Without Self-reported Reference Wages*

Adrián de la Garza [†] Giovanni Mastrobuoni [‡] Atsushi Sannabe [§]
Katsunori Yamada [¶]

Abstract

This article makes three main contributions to the economics of happiness literature. First, using a novel data set of about 90,000 Japanese workers surveyed in annual cross-sections between 1990 and 2004, it demonstrates that individuals experience strong disutility when they perceive that their coworkers earn relatively higher wages. In contrast with other tests of the relative utility hypothesis in the literature, our estimation relies on workers' self-reported beliefs of their peers' wages, which we argue are more closely aligned to the "true" reference-group benchmark than the assumed comparison income measures employed in other studies. Second, the article shows important heterogeneous effects of both absolute and relative income on happiness. In particular, workers who are better able to accurately predict their peers' wages seem to experience both greater utility of higher own income and greater disutility of higher relative income. Third, we assess the validity of different methodologies that the literature has employed to construct comparison income measures and find significant discrepancies, particularly when reference income is derived from Mincer equations—a common approach in other studies. We demonstrate that such discrepancies stem from the difficulty in finding valid exclusion restrictions that help identify the relative income effect on happiness. In the absence of self-reported reference wages, we propose a simple IV strategy that does not eliminate the lack of consistency but delivers a lower bound of the "true" effect.

Keywords: Subjective well-being; relative utility; reference wages.

JEL classification: D00; J28.

1 Introduction

The relative utility hypothesis (Duesenberry 1949) posits that individuals derive utility not only from their own levels of consumption but also from how much they consume relative to a well-defined benchmark group. The empirical evidence accumulated over the last twenty years has generally found support for this theory, extensively documenting a negative relationship between an individual’s reported level of happiness and the income or wages earned by his peers.¹ However, there still seems to be less of a consensus about the magnitude and economic significance of these relative effects, among other things, because of the many approaches to define comparison income.

A common approach, for example, is to estimate a Mincer equation that allows the econometrician to predict the wage of an individual with given characteristics. This predicted wage then becomes the relative measure to which individuals allegedly compare. An alternative method is to calculate average wages by cells or groups defined by age, gender, education level, and other particular individual characteristics. In general, all of these approaches implicitly assume that individuals compare themselves to a hypothetical “average” individual with given characteristics and that they infer their peers’ wages the way econometricians do (Manski 1993; Sloane and Williams 2000). More specifically, each method has potential drawbacks. For example, studies that recur to the Mincer solution must identify the reference wage effect on happiness by including additional variables in the wage regression that are excluded from the happiness equation—exclusion restrictions that are frequently unjustified and easily refutable.

This paper makes three main contributions to the economics of happiness literature. First, it empirically tests the relative utility hypothesis by means of a novel data set of about 90,000 Japanese workers surveyed in repeated annual cross-sections between 1990 and 2004. The data contain information on workers’ reported perceptions of their peers’ wages, which we argue are more closely aligned to the “true” reference-group benchmark than the assumed comparison income measures found in the literature. Our analysis demonstrates the existence of significant (and negative) relative income effects on reported job satisfaction and overall happiness. These results hold even when controlling for a rich-enough list of covariates—including workers’ own absolute income—and addressing the possibility of endogenous self-reported reference wages due to underlying pessimism that could, in principle, be correlated with individual subjective well-being measures.

Second, the article shows important heterogeneous effects of both absolute and, especially, relative income on reported well-being. In particular, workers who are better able to accurately predict their peers’ wages seem to experience both greater utility of higher own income and greater disutility of higher relative income. We associate these results with feelings of jealousy—as in Dupor and Liu (2003)—and with workers’ access to information about job offers and the wage structure in their profession.

Third, we assess the validity of different methodologies that the literature has employed to construct comparison income measures. One of the advantages of our database is that its rich structure allows us to define reference income in ways that are similar to what previous studies have done. We then employ three alternative definitions that are widely

¹Section 2 discusses the literature in more detail.

used in previous studies and re-estimate the model. Our findings show that, in all three cases, the estimated relative income effects are not consistent with results obtained when self-reported reference wages are used as the comparison income measure. In one particular case, when reference income is defined using Mincer-predicted wages, the estimated absolute and relative income effects are highly unstable. We interpret this result as evidence of the difficulty in finding valid exclusion restrictions that are helpful to identify the relative income effect on happiness. Next, we estimate the bias in these estimates by means of a generalized version of the classical measurement error model and show that the direction of the bias is ambiguous. We propose a simple instrumental-variables strategy that can be implemented when self-reported comparison wages are not available. This approach does not eliminate the measurement error bias, although it delivers a lower bound—in absolute value—of the impact of reference wages on well-being.

Additionally, our paper also documents the relationship between subjective well-being and individual characteristics of workers in Japan. Our analysis compares these results with those in previous studies, which have focused primarily on the U.S. and the western European labor forces. Our findings confirm several standard results in the happiness literature. For instance, women and married workers tend to report higher levels of satisfaction than men and single individuals, respectively. However, we also observe a U-shaped relationship between satisfaction and educational attainment, which contrasts starkly with the monotonically increasing association in the U.S. and Europe found in past studies. Given that, to the best of our knowledge, our paper is one of the first happiness studies in Japan, an additional contribution to the literature is to help in the construction of a set of stylized facts that may be generalizable to cultures outside of the West.

The paper is organized as follows. Section 2 provides a brief synthesis of the literature and motivates the present study. In Section 3, we present our empirical framework to test the relative utility hypothesis, introduce our data, and explain how they differ from previous data sets on job satisfaction and happiness. Section 4 presents our main results focusing on the use of workers' expectations on their peers' wages as our primary comparison income measure. In Section 5, we re-estimate the model employing alternative metrics used in the literature and compare the results. We also demonstrate from a theoretical standpoint why the bias present in estimations that employ these theoretical constructs as reference income proxies may go in either direction and propose our instrumental variables approach to bound the reference wage estimate. Finally, Section 6 presents some concluding remarks.

2 Motivation

2.1 Literature Overview

The last twenty years have seen an increasing interest in the economics profession to investigate the relative utility hypothesis: the idea that individuals derive negative utility when people around them obtain a higher income. In spite of a few disputes in the earlier literature regarding the sign and significance of this correlation, there now seems to be a general agreement of a negative association between comparison income measures—such as wages earned by relatives or work colleagues—and subjective well-being—for instance,

self-reported feelings of job satisfaction or overall happiness.² More recent studies, however, have instead focused on providing an answer to one main question: what exactly is the appropriate comparison income measure?

There are at least two dimensions to this question. First, what is the relevant reference group? As Clark et al. (2008) have pointed out, the bulk of the literature has defined comparison income as that earned by people with similar individual characteristics. However, it is not clear what the relevant characteristics are. Reference group definitions vary widely among different studies, from somewhat specific groups such as colleagues (Cappelli and Sherer 1988; Rizzo and Zeckhauser 2003; Brown et al. 2008; Clark et al. 2009b), friends (Senik 2009), relatives (Senik 2009), and neighbors (Luttmer 2005; Clark et al. 2009a; Knight et al. 2009; Senik 2009) to more general ones such as “someone like you” (Clark and Oswald 1996) and “a representative person in society” (Easterlin 2001; Stevenson and Wolfers 2008). The difficulty in correctly defining a reference group is well identified in Loewenstein et al. (2003) and Luttmer (2005), when they argue that comparison groups are subject to change depending on the different circumstances that give rise to such comparisons in the first place: “If a person buys a small house in a wealthy neighborhood in part because it has a certain status value in her apartment building, she may not fully appreciate that her frame of references may quickly become the larger houses and bigger cars that her new neighbors have” (Loewenstein et al. 2003). Clark and Senik (2010) find that, when it comes to income comparisons, people most often compare themselves to coworkers—although the distribution of answers may change depending on people’s characteristics.³ For instance, individuals who are more prone to meet socially are more likely to declare that they compare to friends, instead of colleagues. Moreover, comparisons to friends, although less widespread, may have a greater impact on people’s utility. Nonetheless, the general conclusion is that what most people have in mind when they compare their income to others, is their colleagues.

Assuming the researcher chooses the appropriate reference group, the second issue that researchers have to deal with is, how to measure comparison income? Most of the literature has relied on three different methodologies, namely: (i) predicting individual wages from Mincer equations (Clark and Oswald 1996; Sloane and Williams 2000; Lévy-Garboua and Montmarquette 2004; Senik 2004); (ii) calculating cell averages according to specific individual characteristics within-sample (Ferrer-i Carbonell 2005; Akay et al. 2012), or (iii) out-of-sample from external data (Cappelli and Sherer 1988; McBride 2001; Luttmer 2005; Clark et al. 2009a; Card et al. 2012). Consistent with several of the reference group definitions mentioned above, all of these approaches imply comparisons with

²An excellent source that documents this negative correlation and provides further detail on the developments, validity, and applicability of happiness measures in the economics literature, see Kahneman and Krueger (2006). A few empirical papers have shown a positive relationship between reference income and satisfaction (or happiness), which has been justified by Hirschman and Rothschild’s (1973) “tunnel effect” conjecture, whereby rising inequality may increase individual well-being if it is interpreted as a positive signal with respect to likely future outcomes (see, for example, Senik (2004)). Nevertheless, our reading of the literature is that the consensus correlation between these two variables is negative.

³Yamada and Sato (2010) find that coworkers are, after friends, the second most common group against which Japanese individuals compare. However, their sample differs from ours, for example, because the dataset we employ focus exclusively on working individuals, while theirs includes students and the unemployed, who are inherently less likely to compare to work colleagues.

other people that share some of the same features as the surveyed individual—“someone like you,” in the Clark and Oswald (1996) sense. However, these methodologies also present some potential problems. First, it is not clear that the individual traits that researchers choose to construct reference income measures are necessarily the ones on which individuals base their comparisons. For instance, why is it that Sloane and Williams (2000) use hours worked but exclude the age of an individual to compute their reference income variable, while Clark and Oswald (1996) do the exact opposite?⁴ Moreover, given the need to first construct a comparison income measure and then estimating a happiness equation, these methodologies rely heavily on potentially questionable identification assumptions. In particular, Mincer regressions from which the predicted reference income measures are derived must include variables that are excluded from the satisfaction equation—an exclusion restriction that is often not warranted. Finally, all of these methods presume that individuals compare themselves to some average, which, as discussed below, it may not necessarily be the case. In the particular case of studies favoring the Mincer approach, estimating comparison income by imputing peers’ wages from wage equations implicitly assumes that individuals will infer peers’ wages the way econometricians do (Manski 1993; Sloane and Williams 2000). This supposes a degree of sophistication that may not accurately reflect the mental process an individual goes through when comparing to his peers.

This paper departs from the core of the literature by employing self-reported reference wages as an alternative comparison income measure. The only two other relevant studies that, to the best of our knowledge, have used direct reference income comparisons—so that the benchmark is not chosen arbitrarily by the researcher—are by Knight et al. (2009) and Senik (2009). The first of these two papers exploits the results of an especially-designed module on subjective well-being in China’s 2002 National Household Survey in order to show that happiness depends on relative income, both when defined with respect to a well-defined contemporaneous reference group and when compared to an individual’s own past income. In particular, respondents are asked to compare their current living standard both with the average standard in their village and with their own standard five years ago. These answers are then classified in one of five possible bins that range from “much below average” to “much above average” and then corresponding dummy variables are used in a standard OLS regression of happiness on conventional individual characteristics and economic variables. The results show that, under any comparison income definition, the relationship between happiness and reference income is negative for people who consider themselves below average in any degree, while the opposite holds true for people who believe they are above average. Analogously, Senik (2009) also provides evidence in support of the relative utility hypothesis using the results of the *Life in Transition Survey* conducted in 28 post-transition countries and Turkey in 2006. In this survey, respondents are asked to compare their current living standard with respect to several reference groups, including their parents’, their former colleagues’, their former schoolmates’, and their past selves’ in the pre-transition period (i.e., before 1989). Although the database does not seem to allow comparisons with potentially relevant contemporaneous groups—such as *current* coworkers or neighbors—Senik’s analysis concludes that “internal benchmarks” created by one’s own trajectory have the

⁴Table A-1 sums up how various papers that rely on different methodologies go about constructing their reference income measures and estimating their happiness equations.

greatest impact on subjective well-being, followed by comparisons to former colleagues and schoolmates. Another novel finding in Senik’s paper is that unfavorable comparisons seem to exert a stronger effect on individuals’ perceived well-being than favorable ones, a result that the author interprets as evidence of loss aversion and a manifestation of adaptation.

Similar to the two previous studies, our approach to testing the relative utility hypothesis also relies on a subjective measure of reference income. The data are obtained from a survey of about 90,000 workers in Japan between 1990 and 2004, in which each respondent is asked what he thinks is the average wage of other employees who are the same age and doing the same job as him.⁵ Note that, in contrast with the ordinal nature of the comparison income variable in Knight et al. (2009) and Senik (2009), ours is a cardinal measure, which should facilitate the interpretation of results regarding the economic impact of comparison income on subjective well-being. In any case, however, we believe that the use of direct comparison income measures overcomes several of the issues that prevail in studies that rely on researcher-based benchmarks.

2.2 Motivating the Use of Direct Comparison Income Measures

One of the evident advantages of the self-reported reference measure over the traditional comparison income variables employed in the literature, is that individual *perceptions* of an event are more closely related to the emotion that such an event may produce in a person—and hence to any related feelings of happiness or satisfaction. To be clearer, if we believe that there exists a negative relationship between the feelings of happiness of person i and the income earned by other people surrounding such person, it must be *because* that person somehow observes this. If individual i is ignorant about a given increase in other people’s income, why would this produce in him any unhappiness, dissatisfaction, or any other such feeling that relates to individual disutility?⁶

To illustrate this with an example, suppose that there exists a society in which there are some very rich and some very poor people. Suppose further that, in this very unequal world, individuals do not perceive this inequality—maybe because there is a very progressive tax system in place, or because the rich are huge philanthropists that somehow transfer resources to the poor, or simply because people do not care: what others earn is not part of their utility function. In this case, there is a disconnect between actual wages and perceived wages: actual wage disparities can be large, but people may not perceive them as such and will therefore not be emotionally or psychologically affected by them. That is, they will not derive any utility or disutility from any fluctuation in other people’s earnings.

The above example attempts to elucidate one way in which individual perceptions of other people’s wages may be more relevant to happiness than a simple average of actual wages of people with certain observable traits. But there are other ways in which this relationship between self-reported reference income and happiness may prove more truthful and economically relevant than between theoretical comparison income measures and subjective well-being. For instance, suppose now that everybody in the world earns exactly the same

⁵Further details on the sample, the specific questions asked, and their format are provided in Section 3.

⁶Card et al. (2012) in fact show that disclosing information on peers’ salaries influences workers’ job satisfaction.

wage, so there is zero variation in wages. Suppose also that in this ultra-egalitarian world, there is also a great deal of misinformation, and some people think that their peers earn more than they do, while others think that their peers earn less. This may be, for example, because in spite of having the same actual income, people choose different consumption bundles, and so one person may be more frugal and save 50 percent of his income, while another may spend this same 50 percent on a bigger house or a fancier car. In this case, even if you know that wages do not vary across individuals, you may observe some significant variation in perceived wages.

Now, given that there is zero variation in wages, you should never observe any correlation between true reference wage and happiness. However, given that perceived wages do vary—and assuming happiness also varies across individuals—you may observe some correlation between these two variables. Suppose that this correlation is negative (controlling for other variables), as we observe in our data set. This negative correlation could arise for several reasons. For instance, people may derive (lose) satisfaction from knowing/believing that they earn more (less) than their peers. An alternative explanation, which need not overrule the previous one, is that happy/optimistic (sad/pessimistic) people may tend to think that they earn more (less) than others.⁷ Although we acknowledge the lack of good instruments that may serve to identify the direction of causality from reference wages to happiness, we argue, in agreement with the literature, that the main channel of this negative correlation between these variables is the first one. We try and rule out the alternative direction by running a regression of happiness on perceived wages, controlling for pessimism variables, interacting these with perceived wages, and showing that the main effect still remains.

The above examples should help to justify the economic relationship between self-reported reference wages and happiness. If we want to learn about what makes people happy and if we want to provide policymakers with more information about what they can do to make citizens happier, then it becomes clear that the relationship between these two variables is worth exploring. In the previous case, where there is zero variation in wages but people do perceive certain differences in wages that influence their happiness, perhaps we could say that policymakers could make greater efforts to inform people better.

To be fair, we should recognize that the world probably does not operate like either of the two examples above. The point of these examples, however, is to emphasize that, irrespective of the distribution of actual wages, what matters to people’s sense of happiness and overall satisfaction—in the sense of Duesenberry (1949), Dupor and Liu (2003), and the jealousy and “Keeping up with the Joneses” economics literature) is their perception of the world. If there is a connection between such perceptions and the actual world, all the better: in this case, we can use actual data (such as actual wages) and not individual perceptions to determine how happy or satisfied people are. But this connection is not necessarily obvious, and in this sense, we believe that a worker’s perception should be more closely aligned to his reported level of happiness than some *ad hoc* comparison income measure, such as the average wage of other workers sharing some of his individual characteristics.

Of course, our subjective reference income variable is not perfect and there are some

⁷Of course it could also be that this negative correlation is due to some third variable that correlates positively (negatively) with happiness and negatively (positively) with perceived wages. We discuss these possibilities later in the paper.

caveats that should be kept in mind. In particular, these subjective data are obtained by asking workers to compare themselves to other workers of the same age and doing a similar type of job. Workers may then provide an answer that corresponds to their belief of the wage earned by this specific reference group, but this may not correspond to the reference group they generally compare with, say, on a daily basis, and which may have a stronger connection with their feelings of happiness and well-being. Nonetheless, given the long hours worked by Japanese individuals in our sample, we believe that other co-workers and colleagues are the most natural reference group to which Japanese workers may compare. This, in fact, is in agreement with the literature, which has consistently shown that co-workers is one of the groups to which individuals most often compare (see, for example, Clark and Senik 2010). Thus, although important, we believe this issue is relatively minor and should not affect our results. In the next section, we introduce the model and discuss the data and this particular issue a bit further.

3 Empirical Framework and Data Description

In order to examine the impact of absolute and relative wages on subjective well-being, researchers typically estimate the following regression:

$$(1) \quad \text{SWB}_i = \alpha_1 y_i + \beta_1 \bar{y}_i + \mathbf{x}_i' \gamma + u_i,$$

where the dependent variable SWB_i represents a measure of worker i 's subjective well-being, such as happiness or job satisfaction. This proxy for utility is assumed to depend on the worker's (log) wage, y_i ;⁸ a (log) reference wage that workers use as a benchmark to determine how well they do relative to their peers, \bar{y}_i ; and a vector of individual characteristics, \mathbf{x}_i , that includes age, tenure, gender, educational attainment, marital status, among other socio-demographic factors. As usual, the term u_i corresponds to an idiosyncratic error term.⁹

One advantage that we have over previous studies is that our dataset contains information on workers' actual perceptions about their peers' wages. As discussed in Section 2, we

⁸Unless otherwise noted, all wages are in logs.

⁹This specification can be thought of as a reduced-form version of a standard utility function of the form:

$$U = U(c, \bar{c}, h),$$

where c is individual consumption, \bar{c} is the level of consumption of a comparison group, and h is hours worked. The theoretical literature has investigated how much keeping-up-with-the-Joneses ultimately matters to consumers and what role social status plays in determining individual utility levels. These studies find that, in addition to their own levels of consumption, individuals care about their peers' consumption levels and their wealth rank relative to their comparison group, which validates the use of reduced-form models such as equation 1. For instance, see Cole et al. (1992); Corneo and Jeanne (1997); and Yamada (2008). Boskin and Sheshinski (1978) and Oswald (1983) theoretically analyze tax policy implications of relative utility, while Abel (1990); Bakshi and Chen (1996); Galí (1994); and Campbell and Cochrane (1999) examined such relative effects on asset pricing. Frank (1985) and Frank (2005) show that relative concerns are more important for positional goods consumption than other goods such as leisure, and that the structure of utility functions with relative concerns over different types of goods is of key importance in the valuations of social welfare.

believe that these self-reported reference wages are more closely aligned to the true benchmark that workers use to compare themselves against their peers. We can thus estimate equation 1 by standard methods¹⁰ and obtain a more precise measurement of the effect of relative wages on subjective well-being.¹¹ We present these findings in Section 4. Our data also allow us to compare our results to the ones we would have obtained had we followed the alternative methodologies that Manski (1993), Sloane and Williams (2000), and others have deemed potentially flawed. These findings are reported in Section 5.

3.1 Data Description

Our dataset comes from the Comprehensive Survey of Labor Union Members, which was designed and administered by a group of psychologists at the International Economy and Work Research Institute. It comprises repeated cross-sections on about 90,000 union members working in Japanese firms listed on the Tokyo Stock Exchange (TSE) from 1990 to 2004. The survey requests that respondents provide self-assessments on their individual well-being at work and in life in general. In addition to this, other questions attempt to obtain information on workers' perceptions of their work environment.¹² The dataset also allows us to control for individual demographic and socioeconomic characteristics, which include age, gender, educational attainment, marital status, annual wage level, overtime hours worked, and workers' expectations of their peers' wages.

After cleaning the data and removing some inconsistencies, we are left with 78,136 observations.¹³ Table 1 shows some statistics that describe our dataset. Workers in our sample are young with an average age of 35 years. Their average tenure is 14 years, which suggests relatively low mobility in the Japanese labor force. Moreover, union workers in Japan seem to be well-educated in general, as almost all of them have graduated from high school, close to 50 percent have some college experience, and 36 percent have completed at least a university-level degree. We also observe that 58 percent of workers are married and work an average of 23 hours of overtime per month. All of these individuals are regular full-time employees and union members. About one-third of them holds blue-collar positions and

¹⁰Given the discrete, hierarchical nature of the dependent variable, the vast majority of happiness studies in economics have estimated equations similar to 1 using ordered logit or probit estimators. However, it is not clear that these methods are superior to ordinary least-squares since additional assumptions required for these estimates to be valid—such as that of parallel slopes—are often not met. Further, Luttmer (2005) showed that results from happiness equations obtained by OLS are virtually indistinguishable from those obtained by ordered models. Our OLS estimates in Section 4 facilitate the interpretation of the coefficients, although ordered probit estimates are also reported in the robustness section for completeness.

¹¹This of course requires that the typical exogeneity assumptions hold. Our robustness tests in Section 4 address the possibility that wages are endogenous.

¹²The full list of question categories is available in an earlier version of this paper; see Appendix 1 in de la Garza et al. (2008)

¹³The reduction in the number of observations is mainly due to missing information for some of the variables used in the empirical analysis. Observations that showed inconsistencies in the data, such as the worker's tenure being greater than his age, were also dropped from the sample. To ensure that these problems were not due to sample selection on observable characteristics, we compared the full-sample and the working databases along different dimensions including age, education, wages, and reported levels of happiness and job satisfaction. We are *happy* to report that we were unable to find any statistically significant differences between the two datasets.

close to one-fifth of them performs some managerial role in the company. These numbers do not intend to provide an accurate depiction of the representative Japanese worker since, as described above, the survey was administered exclusively to union members employed by major publicly-traded companies. Thus, the results below may not be generalizable to the entire Japanese labor force—for instance, our dataset does not cover employees in high administrative positions as they are not allowed to take part in unions. Nonetheless, due to the large size of our sample and the breadth of coverage of 62 firms across a variety of industries from food to electronics to finance, we believe that this dataset does capture significant features of the Japanese labor market.

One additional consideration is that our database underrepresents women in the Japanese labor force. According to the World Bank’s World Development Indicators, women represent about 40 percent of the country’s working population; in contrast, the share of female participation in our working sample is only 22 percent. This is an important issue because male and female workers differ significantly along several dimensions. Table 1 shows some of these gender differences in terms of observable characteristics, such as education and marital status. For instance, while 40 percent of the male subsample obtained a college degree, only 20 percent of the female group achieved this goal. Interestingly, the fraction of married men is twice the proportion of married women (66 percent vs. 33 percent). Since the literature has found significant correlations between various subjective well-being measures and individual characteristics such as gender, educational attainment, and marital status, pooling the male and female subsamples in our analysis may lead to results that would differ had we considered these two groups separately. We thus keep this distinction in mind and discuss these differences accordingly.

3.1.1 Subjective-Well Being

Each respondent provides information on his own subjective well-being by choosing one of five possible categories, from “least satisfied” (category 1) to “most satisfied” (category 5). We employ primarily two distinct subjective well-being measures, life happiness and job satisfaction, which present some significant differences.¹⁴ First, the correlation between the two is only 27 percent. As Figure 1 suggests, the distribution of life happiness is more spread out and more skewed to the left than that of job satisfaction. Since the literature has utilized a wide variety of subjective well-being measures, the availability of these two variables allows us to test the robustness of our results. For brevity, the empirical analysis below highlights our findings utilizing life happiness as the dependent variable. However, our results are robust to the use of job satisfaction as an alternative proxy for subjective well-being.¹⁵

¹⁴At the beginning of the questionnaire workers are first told “from now on, we would like to ask about your general happiness,” and are asked to report whether they agree with the statement “I’m very happy!” in general. Later in the questionnaire, workers are asked to report about their satisfaction with respect to all aspects of their job.

¹⁵The literature has investigated potential “fatigue” and “question-order effects” that may arise in survey responses (McFarland 1981; Schuman and Presser 1996). Although the number of experimental studies on these issues remains small, the general consensus is that order effects are not pervasive in a typical attitude survey and that, although in some cases these effects may be important, it is difficult to determine *a priori*

3.1.2 Workers' Own Wages

The survey also requests that workers mark down their own wage level from a list of 9 categories, where category 1 denotes annual wages of under 2 million yen and category 9 corresponds to an annual income level of over 10 million yen. We measure individual wages as the mid-point in each of the 7 intermediate categories, and use *ad hoc* values for the two extreme categories. Thus, respondents who reported categories 1, 2, ..., 9 as their wage level, were assigned annual wages of 1.5; 2.5; ...; 12 million yen, respectively. Alternative choices do not alter the main results. Additionally, we deflate this nominal measure using the Consumer Price Index to obtain real wages with 1990 as the base year.

One salient feature of wages in our sample of union workers in Japan is that individual characteristics explain an atypically high fraction of the variation in wages. Table 2 shows standard Mincer regressions for men and women, separately. Wage regressions for the male subsample that control for age, tenure, education, hours worked, and marital status, obtain R^2 measures of about 70 percent.¹⁶ In contrast, similar specifications for a sample of U.S. workers would generally yield an R^2 of about 30-35 percent. This high coefficient of determination in the Japanese data may be partly due to the very strict seniority system that prevails in the Japanese labor market.¹⁷ For instance, the correlation between wages and age for the full sample of Japanese workers is 69 percent. Using a comparable sample of unionized workers from the Current Population Survey during the same 1990-2004 period, the corresponding correlation measure for the U.S. is only 21 percent. This high coefficient of determination in the Japanese sample may play to our advantage as it reduces possible concerns that wages may depend themselves on happiness, thus minimizing potential endogeneity issues. We nevertheless address this possibility in Section 4.

3.1.3 Self-Reported vs. Constructed Reference Wages

Survey respondents provide information on self-reported comparison wages by answering the question, "What do you think is the average wage of corporate employees who are the same age as you and doing the same job?" Just as in the case of workers' own wages, answers to this question are originally chosen from a list of 9 categories, then matched with individual wage values according to the category mid-points described above. In contrast with the reference wage measures employed in previous studies, the availability of self-reported comparison wages allows us to gauge how workers perceive their peers' wages.

To better understand the differences between self-reported and constructed wage mea-

what they may be. It has been argued that question-order effects may be avoided if questions on a same topic are spread out in the survey. This and other measures have been taken by the team of psychologists that administered our survey. Given the robustness of our results using two distinct measures of subjective well-being, placed in different sections of the survey, we conclude that question ordering is not an issue within our framework.

¹⁶This feature depends only marginally on wages being reported in categories. When we smooth out wages by adding a disturbance term that is uniformly distributed between each cutoff point, the R^2 statistic decreases by, at most, 5 percentage points.

¹⁷When age-related variables are omitted from an otherwise standard Mincer regression that controls for individual characteristics such as gender, schooling, and marital status, the coefficient of determination decreases to 30-35 percent.

asures, we compare our relative wage measure as reported by the worker to some of the most common reference wage estimates used in other studies. A standard method consists in calculating wage averages by cells or groups defined by a set of given observable characteristics of workers. We define cells in three different ways: by gender and age; by gender, age, and education level; and by gender, age, education level, and managerial experience. Following the literature, we estimate these cell averages from two different underlying data sources: our own dataset, described above, and an external dataset containing wage information of workers with similar observable characteristics. This second approach is most commonly employed in the literature and is useful to validate our results. The external data correspond to wages for individuals working in large companies with over 1,000 employees, as provided by the Basic Survey on Wage Structure (BSWS) released by the Japanese Ministry of Health, Labour and Welfare.¹⁸ A third method that is frequently used in relative utility studies is to estimate Mincer regressions such as the ones showed in Table 2. The theoretical comparison wage measure corresponds to the fitted wage value of the average worker. In what follows we use the prediction from a wage regression that controls for gender, age, education level, and managerial experience—similar to the third cell defined above. When using Mincer regressions to estimate reference wages researchers need to find appropriate exclusion restrictions, meaning at least one variable that influences reference wages but not happiness. Notice that computing cell averages is equivalent to running a Mincer wage regression where the regressors are fully interacted with each other. In this case the identification hinges on these interactions, which, like the exclusion restrictions, are assumed to influence reference wages but not happiness.

The bottom panel of Table 1 displays summary statistics for workers’ own wages and self-reported reference wages, as well as comparison wages defined according to the various methods employed in the literature. The table shows that average wages estimated from the BSWS external database are less than 2 percent higher than self-reported reference wages but about 10 percent higher than workers’ own wages. We attribute this significant difference in the second case to the inclusion of workers with a *general* assistant manager position (*kacho* in Japanese) in the BSWS data. In contrast, our dataset only includes wage information for employees in non-supervisory, assistant manager positions. This technical subtlety evinces how difficult it can be to compare wage averages across different datasets, which may pose challenges to the use of external databases in the construction of reference wage measures. In addition, self-reported reference wages seem to be significantly more disperse than any of the other measures utilized in the literature. Averaging wages across workers with similar given characteristics may not reflect accurately, for example, how undervalued a worker feels in the labor market. This is further confirmed in Figure 2, where we plot the kernel density of various wage measures. Comparing self-reported reference wages and reference wages constructed from an external data source, for example, illustrates a potential underlying pessimism among Japanese workers regarding their beliefs of what their peers earn. If feelings like this are common among workers, studies utilizing such theoretical constructs would underestimate the effects of comparison wages on workers’ self-reported levels of well-being.

The data also hint at a potential underlying pessimism in workers’ perceptions of their

¹⁸The data can be obtained from the following website: <http://www.mhlw.go.jp/english/database/db-1/>.

peers' wages, as suggested by the 10-percentage point difference between self-reported reference wages and workers' own wages. This is an important point since a worker's belief of his peers' wages may be endogenous, for example, if a relatively happier individual has a more optimistic view of his own salary relative to his colleagues'. Conversely, a pessimistic worker may think that he is underpaid with respect to his peers. With panel data, assuming there was enough variation over time in happiness, wages and relative wages, one could difference out time-invariant worker characteristics, such as pessimism, and obtain unbiased estimates of the effect of absolute and relative wages on happiness. As our dataset does not allow us to track individuals over time, we address this problem by using answers to two questions in our survey that are likely to capture workers' pessimistic attitudes along two different dimensions. The first question asks whether a worker believes that his colleagues would help him in times of need; the second question asks the worker if he is satisfied about the possibility of promotion within his company. Controlling for these two effects should capture the level of inherent pessimism of a given worker. Additionally, we could interact these proxies for pessimism with perceived reference wages to capture the potential heterogeneity in workers' perceptions due to pessimistic attitudes. As will be discussed in the next section, these exercises should quell some of the above-mentioned endogeneity concerns.

Having introduced the data, the next section presents the main results. It is important to remark that, in spite of their virtues, self-reported reference wage measures are not a panacea and continue to leave some issues unresolved. For instance, by asking workers to report what they believe that other employees with their same characteristics *and in the same job* earn, the survey restricts workers to confine their reference group to individuals within their same job. Still, on a more regular basis, workers may potentially compare themselves to relatives, friends, or colleagues doing other jobs. Moreover, the relevant reference group may not be stable over time. For instance, a recent graduate may compare himself to other recent graduates; but a person who has been out of school for 10 years may compare himself to former classmates and colleagues, to supervisees and supervisors, and even to former selves.¹⁹ Nonetheless, we believe that self-reported comparison wage data are a superior alternative to reference wage measures constructed from Mincer equations or cell averages. First, as we mention in Section 2, workers' perceptions of their peers wages are more closely related to their overall feelings of happiness, which makes this variable a more suitable candidate for reference income than the theoretical constructs used in previous studies. Second, as Clark and Senik (2010) have shown, coworkers are the most frequent group to which workers compare, which should abate concerns about providing an explicit reference group of coworkers to surveyed individuals. Finally, in stark contrast with the alternative comparison income measures employed in the literature, self-reported reference wages do not limit the worker's reference group to some cell average and do not hinge on disputable identifying restrictions. Studies that use cell averages and Mincer-based reference income measures tacitly assume that individuals compute their peers' wages the way econometricians do, which, as argued in Section 2, is unlikely. Some of the disadvantages of these alternative comparison income variables will become more evident when the model described in equation 1 is re-estimated in Section 5 using these other measures.

¹⁹On this and other related issues, see Senik (2009).

4 Results

To empirically test the relative utility hypothesis, we estimate a version of equation 1 that substitutes our self-reported reference wage measure, \bar{y}_i^* , for the standard proxy used in the literature, \bar{y}_i .²⁰ As discussed in Section 3.1, there are important differences between male and female workers in almost every dimension from wages to hours worked to educational attainment, which justifies our estimation of equation 1 for men and women separately. Pooling the male and female subsamples does not have any significant qualitative impact on our findings. The errors u_i are allowed to be correlated within firms although different clusterings do not affect our conclusions.

The results in Table 3 find strong empirical support in favor of the relative utility hypothesis: holding wages constant, individuals tend to report lower levels of satisfaction when they perceive that their peers' wages are higher. In particular, if a worker believes that his peers' wages have risen by one standard deviation, his happiness level would decrease by 0.10 standard deviations.²¹ On the other hand, the absolute wage coefficient is consistently positive and significant at conventional levels, which implies that a worker's reported happiness increases as his wage goes up. The results suggest that a one-standard-deviation increase in a worker's own wage would lead to an increase in happiness of 0.13 standard deviations. This finding is reminiscent of the conclusion by Alesina et al. (2004) that "money buys happiness." Given that the impact of absolute wages on subjective well-being is stronger than that of relative wages, an across-the-board wage hike of, say, 10 percent would be associated with an overall increase in reported happiness. This finding is confirmed by an F -test that rejects the null hypothesis that the sum of the coefficients on absolute and relative wages is equal to zero at conventional levels.

The absolute and the relative wage effects are substantially larger for males. A comparison between columns 5 and 6 shows that both the absolute and the comparison wage coefficients are about 35 to 50 percent stronger for men. This implies that women do not appear to derive as much utility as men do either from their own labor earnings or their perception of their peers' wages.²² Nonetheless, in agreement with the literature, women generally report higher levels of life satisfaction *ceteris paribus*, as the results for the pooled sample in column 7 suggest.

Individual worker characteristics explain a significant amount of the variation in reported levels of life satisfaction. For instance, in the case of males, the inclusion of age, educational attainment, marital status, and dummies for whether the worker has a blue-collar position and whether it performs any managerial tasks in the company, increases the coefficient of determination of the regression from 2 to 7 percent.²³ The inclusion of these individual

²⁰Section 5 discusses the consequences of estimating equation 1 using a mismeasured version of the "true" relative wage benchmark used by workers.

²¹The direction and magnitude of this estimate is consistent with the findings in Yamada and Sato (2010) from a hypothetical choice experiment done on Japanese individuals.

²²We purposely are cautious in comparing results for men and women as Conti and Pudney (2011) have shown that survey design might differentially influence the way men and women respond to questions about happiness.

²³Many previous studies control for both age and tenure in subjective well-being regressions. In our case, we opt to exclude tenure as a regressor because of the high correlation of this variable with age due to the characteristic seniority tenure system in the Japanese labor force described in Section 3.1.2.

worker characteristics reduces the absolute wage coefficient by about 22 percent, although the impact of wages on happiness remains positive and strongly significant. Such reduction in the magnitude of the own wage coefficient is unsurprising given that standard Mincerian analysis has proven these individual characteristics to be important determinants of wages.

Pessimism seems to be an important individual trait that affects a worker's sense of well-being.²⁴ Pessimistic attitudes about the helpfulness of co-workers and about the possibilities of job promotions have large and significant negative effects on life satisfaction. These effects are of similar magnitude for both men and women. As discussed in Section 3.1, the inclusion of these two pessimism variables attempts to minimize concerns about wage endogeneity. Controlling for pessimistic attitudes leads to small decreases (in absolute value) in the magnitudes of both the own and the comparison wage coefficients. However, in both cases, the direction and magnitude of each of these effects are preserved. Additionally, these two pessimism variables by themselves explain an extra 4 percent of the variation in life satisfaction, which corroborates the relevance of a worker's individual characteristics in the determination of subjective well-being.

To verify that the relationship between happiness and both absolute and relative wages is not spurious, we investigate other channels through which these links may arise. Things like a company's wage structure, pay raises, and worker mobility within the establishment may affect how satisfied workers are with the salary they and their co-workers perceive. For instance, several authors have argued that high average wages within the company may provide a signal to the worker about his ability to rise within the firm's wage ladder (Hirschman and Rothschild 1973; Manski 2000; Senik 2004; Clark et al. 2009b). If the worker believes that he has greater possibilities of increasing his compensation in the future, the negative impact of higher peers' wages would decrease in absolute terms. In other words, omitting average wages in a happiness regression would overestimate the comparison wage effect. Moreover, greater wage dispersion within the firm may also have a significant impact both on satisfaction and on the effect of absolute and relative wages on happiness. For instance, if workers know that there is greater variance in compensation packages offered by their company, that may influence how they feel about their relative rank in the wage spectrum (Brown et al. 2008).

We explore these possibilities by controlling for the logarithm of average wages and the interquartile range of log wages within the firm. As expected, higher average wages have a positive effect on reported levels of life satisfaction—although this effect is statistically significant only in the case of male workers. In contrast, greater inequality has a negative and significant impact on happiness for women, while it has no effect on men. Using the pooled sample, neither mean wages nor wage dispersion have a statistically significant effect on life satisfaction. In all cases, the inclusion of these variables has no discernible impact on the own wage and the reference wage coefficients; that is, the relative utility results continue to hold.

²⁴On a related issue, Stutzer (2004) found that higher income aspirations reduce individuals' life satisfaction. See also Frey and Stutzer (2010).

4.1 Heterogeneity in Wage Effects

We have now confirmed that the negative correlation between reference wages and subjective well-being holds even after accounting for a number of individual worker characteristics and controlling for other factors that may potentially explain away this relationship. In this section, we now explore in further detail one additional possible mechanism that may link these two variables.

Perhaps the most logical or straightforward reason that may justify such relationship is jealousy. In our case, jealous workers experience lower utility levels when they perceive that their peers earn more than they do.²⁵ Workers who like to compare themselves to other workers or who care about what their peers earn are likely to be better informed about the prevalent wage differentials at any given time. If this is true, workers who make smaller prediction errors should suffer greater disutility from any increases in wages earned by their peers.

To test this, we first calculate a worker's wage prediction accuracy and then estimate the impacts of comparison wages on his reported levels of life satisfaction. We define such prediction accuracy as the percentage difference (in levels) between the peer wage reported by the worker (i.e., his belief) and the wage average within each worker group or cell identified by the age of the worker, his gender, and his education level.²⁶ We sort the whole subsample of male workers by their prediction accuracy, and then group them into four broad categories, ranging from worst (i.e., 1st quartile of workers) to best (i.e., workers in the top 5 percent of predictors). Finally, we re-estimate the SWB equations for each of these groups, including the full set of controls that were accounted for in column 5 of Table 3.

The results appear in Table 4. The estimates corroborate our initial hypothesis that better predictors are more severely affected by changes in their peers' wages. Those who fare worst at predicting the wage of other workers with similar characteristics, do experience negative disutility from an increase in their peers' wages, although this effect is smallest relative to that of other workers who are more accurate in their predictions. The differences in these reference wage effects over well-being are large. For instance, workers in the top 5 percent according to their prediction accuracy experience a negative impact on life satisfaction that is 5 times as large as that reported by workers in the bottom 25 percent of the sample (-0.21 for worst predictors vs. -1.06 for best predictors). Such a large effect for workers whose reference wage is very close to the predicted one is also additional evidence that pessimism, which would drive these two wage measures apart, cannot explain our results.

Moreover, good predictors not only care more about their peers' wages, but also about *their own*. The differences in these own wage effects are also relatively large: about three times as large for best predictors compared to worst predictors. Nonetheless, these increases in the own wage effect as workers' prediction accuracy improves are not as marked as those observed for reference wages. One possible interpretation of this finding is that better predictors experience stronger feelings of jealousy, and so increases in their peers' wages will

²⁵The economics literature has traditionally defined jealousy in a similar way. See for example, Dupor and Liu (2003).

²⁶Although we continue to focus on the male subsample only, in this calculation we control for gender because we expect male workers to compare themselves more often to other male, not female, peers.

outweigh any increase in well-being they may get from a similar rise in their own wage. In turn, this result may imply that workers who care more about their peers' and their own wages will be more likely to be better informed about job offers and the wage structure in their profession.

As an additional remark, the estimates in Table 4 suggest that one cannot ignore cultural differences when comparing reference and own wage effects on well-being across studies that use different samples, especially if the data employed correspond to individuals in different countries. In Section 5.2, we compare our findings with those in previous literature keeping this caveat in mind. Before we do that, we corroborate the robustness of our results in the following section.

4.2 Robustness Checks for Self-reported Reference Wages

For brevity we show our robustness checks for the male sample only. Table 5 shows that our main results hold when we consider alternative specifications. For the sake of comparison, column 1 shows our preferred specification from Table 3, which includes individual characteristics (not shown), underlying pessimism, and firm's average wages and wage dispersion, with the addition of industry fixed effects. As is shown in column 2, accounting for year fixed effects leaves our main results unchanged.

In column 3, we address the possibility of endogeneity in both workers' own wages and reference wages. First, exploiting the Japanese seniority system, we instrument worker i 's own wage with the average wage of his coworkers that are of the same age; the average is calculated using all workers of the same age, working in the same company, but excluding the wage of worker i .²⁷ This strategy is valid as long as the proposed instrument affects happiness only through individual i 's own wage. The estimates in column 3 show that the coefficient on own wage is in absolute value slightly smaller but still significantly different from zero, and the same is true for self-reported reference wage. The own wage coefficient is still larger than the one on self-reported reference wages, but partly due to the increased standard errors we cannot reject the two coefficients to be the same. Next, in column 4, we contemplate that a worker's reference group might depend on the company the worker chooses to work for, and unobserved amenities within the company might be correlated with both wages, reference wages, and happiness. Even though these companies are large²⁸ and might thus have more than one establishment, company fixed effects should also capture average neighborhood characteristics. The results show that this is not the case and that controlling for company fixed effects does not alter the main findings.

In column 5 we perform a horse-race between self-reported reference wage and the reference wage from external data (see Section 3.1.3). The coefficient on the external reference wage has the right sign and is significantly different from zero, but, most importantly, the coefficient on the self-reported reference wages is practically unchanged. One possibility for

²⁷If we assume that the wage of individual i working in company j is given by: $y_{ij} = f_j(\text{age}_i, \text{education}_i, \text{tenure}_i) + \text{ability}_i$, then we can instrument this wage as $f_j(\text{age}_i, \text{education}_i, \text{tenure}_i) \approx \frac{1}{N_{ja}-1} \sum_{l \neq i} y_{lja}$.

²⁸We observe approximately 90,000 workers and 62 firms, which means that each company has on average 1,500 workers.

the negative sign on the external reference wage is that it proxies for the worker's permanent wages. The *difference* between the own wage and the external reference wage will thus proxy for unexpected positive shocks to income.²⁹

In column 6, we use an ordered probit instead of the OLS. The coefficients are not directly comparable with the OLS ones but the relative size of the coefficient on wages and the one on reference wages can be compared and the interpretation remains the same.³⁰ This result is in agreement with findings by Luttmer (2005) that the use of least-squares estimators in happiness studies does not impact negatively the general conclusions, even when ordered probit or logit models would be methodologically preferred given the hierarchical and non-linear nature of the dependent variable.

Finally, column 7 shows that using job satisfaction as our subjective well-being measure does not alter the main findings: the coefficient on absolute wages, although slightly smaller in magnitude, is positive, strongly significant, and greater in absolute terms than the reference wage coefficient. As expected, the latter estimate is negative and significant at the 1 percent level. Taken together, these alternative specifications corroborate the stability of the results emphasized throughout the section.

5 Testing the Relative Utility Hypothesis Using Constructed Reference Wages

In the previous section, we used reference wages reported by workers to demonstrate how robust is the negative relationship between these self-reported reference wages and well-being. However, self-reported reference wages are not always available. Instead, most tests of the relative utility hypothesis found in the literature generally rely on reference wage measures constructed as some average wage defined in various ways, as discussed in Sections 2 and 3. In this section, we investigate whether these alternate wage measures deviate from the comparison wage benchmark truly perceived by workers, and if so, whether these differences introduce any significant biases in the estimated impacts of reference wages on well-being.

To preview our results, the findings below show that, in general, the estimated effect of reference wages on well-being is not consistent when using constructed reference wages as proxies for the truly perceived comparison wage. Although the theory suggests that the direction of the bias introduced cannot be determined, our empirical estimates show slightly smaller reference wage effects when we define this comparison wage variable using different types of cell averages. However, when reference wages are constructed from Mincer regressions, the estimated effects are vastly different from those suggested by all of our previous estimates, and highly unstable. We attribute these significant discrepancies to the difficulty in finding valid exclusion restrictions to justify the Mincer approach.

²⁹We thank Angus Deaton for pointing out this possibility.

³⁰Nevertheless, the coefficients turn out to be similar in magnitude to the OLS case partly because the root mean squared error of the baseline regression is 1.04 and thus close to unity, to which the error term in the latent model of the ordered probit is normalized.

5.1 Revisiting the Subjective Well-Being Regressions

To investigate how the use of constructed reference wage measures may affect the empirical tests of the relative utility hypothesis, we first re-estimate the regressions in Table 3, now substituting the self-reported reference wage variable with the alternate measures used in the literature. The estimates are shown in Table 6. The first regression uses self-reported reference wages and produces estimates similar to the ones shown earlier in Table 3. The coefficients in columns 2-4 are derived from specifications that construct reference wages using various cell definitions. Cell 1 is defined by the age and education level of the worker and the average is computed using our own wage data. Cells 2 and 3 are both defined by the age of the worker, his educational attainment, and whether he is responsible for any managerial tasks within his company. The difference between these two averages is that cell average 2 is also computed from our own wage data, while cell average 3 uses the external BSWs wage database described in Section 3. Finally, the reference wage in column 5 comes from a standard Mincer regression similar to the ones shown in Table 2.

The results suggest that life satisfaction regressions that use constructed reference wages instead of self-reported ones do produce somewhat different results. The top panel illustrates how the raw effects of own and reference wages change when using alternate comparison wage measures, and so these first five specifications do not control for individual worker characteristics. In the case of specifications that use cell averages, both the own wage and the reference wage effects are always about 20-30 percent smaller in absolute value relative to the benchmark estimates. However, although the differences between each of the own wage and reference wage coefficients in columns 2-4 and the analogous estimates in column 1 are statistically significant, all of these coefficients are important in a statistical sense and the suggested directions of these effects are preserved. By contrast, the specification that uses Mincer-constructed reference wages tells a different story. Although the estimated own wage effect is positive and statistically significant, as before, the coefficient is 85 percent smaller than the one derived from a specification that uses self-reported reference wages. Moreover, the estimated impact of reference wages on life satisfaction is more than twice the size of the corresponding coefficient in column 1, *and positive*, which contrasts with the suggested effects in all of the previous specifications.

These findings are echoed in the bottom panel of the table, where we re-estimate the same five equations, this time controlling for worker individual characteristics. As shown in Table 3, the inclusion of these regressors slightly lowers the magnitude of both the own wage and the reference wage coefficients, although the general results are preserved. Once again, the estimates derived from regressions that use constructed reference wages are somewhat smaller in absolute value than the corresponding benchmark coefficients obtained when self-reported reference wages are employed instead. Nonetheless, the own wage effect on life satisfaction continues to be positive, the negative impact of reference wages on well-being persists, and all of the coefficients are strongly significant. The stark difference in the results is given, once more, by the specification with Mincer-constructed reference wages. This time, the size, direction, and statistical significance of the own wage coefficient are almost identical to those obtained using cell averages. Similar to specification 5 in the top panel that did not control for individual characteristics, the estimated reference wage effect under the Mincer approach continues to be positive, although the coefficient is statistically

indistinguishable from zero.

In sum, empirical tests of the relative utility hypothesis that employ reference wage measures constructed by the econometrician imply reference wage effects on subjective well-being that deviate somewhat from those estimated when self-reported reference wages are used. In what follows, we attempt to uncover the reasons behind this bias.

5.2 Estimating the Bias

To better understand the differences described above, we utilize a generalized version of the standard classical measurement error model. Recall that equation 1 gives the relationship between subjective well-being and the reference wage variable, \bar{y}_i . Now, suppose that the reference wage variable employed is a mismeasured version of the worker's correct perception of what his peers earn, \bar{y}_i^* . That is,

$$(2) \quad \bar{y}_i = \alpha_0 + \beta_0 \bar{y}_i^* + \epsilon_i.$$

This represents a generalization of the classical measurement error model, where $\alpha_0 = 0$ and $\beta_0 = 1$. We believe this generalization is appropriate in our case because the data suggest that reported reference wages differ significantly depending on workers' wage levels. For instance, people with low wages systematically perceive that their peers earn more than they do; that is, $\bar{y}_i^* > \bar{y}_i$ for low earners, which would imply that $\alpha_0 > 0$ and $\beta_0 < 1$. Similar to the classical measurement error model, we assume that the error term is orthogonal to the true reference wage, and that the relationship between the latter and the mismeasured variable is linear.

Substituting equation 2 into equation 1 obtains:

$$(3) \quad \text{SWB}_i = \alpha_1 y_i + \beta_1 (\beta_0 \bar{y}_i^* + \epsilon_i) + \mathbf{x}_i' \gamma + \beta_1 \alpha_0 + u_i.$$

In such a model, a bias arises as a function of both the variance of the ϵ residuals and the distance between β_0 and 1. To see this, assume for simplicity that subjective well-being does not depend on worker individual characteristics.³¹ In this case, the probability limit of the OLS estimate of β_1 is

$$\text{plim } \hat{\beta}_1^{ols} = \frac{\text{cov}(\beta_0 \bar{y}^* + \epsilon, \text{SWB})}{\text{var}(\beta_0 \bar{y}^* + \epsilon)} = \frac{\beta_0 \text{cov}(\bar{y}^*, \text{SWB})}{\beta_0^2 \text{var}(\bar{y}^*) + \text{var}(\epsilon)} = \beta_1 \frac{\beta_0}{\beta_0^2 + \text{var}(\epsilon)/\text{var}(\bar{y}^*)}$$

The equation above suggests that, in general, $\hat{\beta}_1^{ols}$ is not a consistent estimator of the true effect of comparison wages on subjective well-being when constructed reference wages are used. This statement is true as long as β_0 is different from $\beta_0^2 + \text{var}(\epsilon)/\text{var}(\bar{y}^*)$. Moreover, unless we can accurately determine whether β_0 is above or below 1, the direction of the bias is ambiguous.

³¹The results below do not hinge on this assumption. Using the Frisch-Waugh-Lovell theorem we could alternatively work with the residuals of a projection onto the space orthogonal to the individual characteristics. Alternatively we can derive the coefficient for \bar{y}^* independently from \mathbf{x} if self-reported reference wages are not dependent on workers' individual characteristics. The data suggest that this is a reasonable assumption. For instance, compare columns 1 and 2 in Table 3, and note that the estimated self-reported reference wage does not change when worker characteristics are introduced.

Can we use instrumental variables (IV) to consistently estimate $\hat{\beta}_1^{ols}$? In the classical measurement error model, an IV estimator would normally get rid of the bias introduced by the mismeasurement of the independent variable. By contrast, in the generalized version of the model, an IV approach does not lead to a consistent estimate of $\hat{\beta}_1^{ols}$, although it does allow us to bound the estimated effect. To see this, suppose that there are two independent proxies of \bar{y}^* , proxy a and proxy b . We can then use proxy a as an instrument for proxy b :

$$(4) \quad \text{plim } \hat{\beta}_1^{iv} = \frac{\text{cov}(\beta_0^a \bar{y}^* + \epsilon^a, \text{SWB})}{\text{cov}(\beta_0^a \bar{y}^* + \epsilon^a, \beta_0^b \bar{y}^* + \epsilon^b)} = \frac{\text{cov}(\bar{y}^*, \text{SWB})}{\beta_0^b \text{var}(\bar{y}^*)} = \frac{\beta_1}{\beta_0^b}.$$

The expression above implies that an IV estimate of β_1 would still be biased, although now this bias depends only on the distance between β_0^b and 1, not on the variance of the ϵ residuals. Taking the ratio between $\hat{\beta}_1^{iv}$ and $\hat{\beta}_1^{ols}$ one can see that whenever OLS and IV give similar results, the signal-to-noise ratio $\text{var}(\bar{y}^*)/\text{var}(\epsilon)$ will be large. Unfortunately, β_0 might still be different from one and bias both estimates. Since workers with low wages tend to report a reference wage that is higher than their own wage, and *vice versa*, the regression of predicted reference wages on self-reported ones shows a positive constant term and a slope that is smaller than one. The IV estimate will thus tend to be larger, in absolute value, than the true coefficient.

Table 7 compares the OLS and the IV estimates. The OLS regressions are identical to the ones that appear in Panel A of Table 6 and are shown to facilitate the comparison with the IV estimates. The four OLS regressions are exactly the same, except that each uses a different reference wage measure. The analogous results for Panel B are not reproduced for brevity. The reported IV regressions instrument for the same reference wage measure employed in the corresponding OLS regression, using a different cell wage average definition as instrument.³² We focus on estimations that use self-reported and constructed reference wages since, as discussed above, these coefficients are stable across specifications. Results that use reference wages derived from Mincer regressions are explored further in Table 8 below.

The findings confirm the corresponding effects that own wages and reference wages have on life satisfaction. In all cases, each of the IV estimates is statistically indistinguishable from the OLS estimate obtained when self-reported reference wages are employed. Looking at equation 4, the direct implication of this is that $\hat{\beta}_0$ is close to 1, and that the IV coefficients do provide a consistent estimate of the effect of reference wages on subjective well-being. Of course, it is possible that this result may not be generalizable to other similar databases measuring well-being and wages for different populations in other regions or countries. A generalized result, though, is that the IV procedure gets rid of one of the sources of bias. In our case, this is shown by the significant differences between each of the IV coefficients and the OLS regression that employs the corresponding mismeasured (constructed) reference wage measure. Moreover, with respect to the own wage effects, we observe that the IV coefficient is always somewhat larger than the corresponding OLS estimate. We attribute this result to the construction of the reference wage measure used in the OLS regressions as

³²The first-stage estimations and the results from several underidentification and weak-instruments tests are not reported for brevity. These results confirm the validity of our instruments and are available upon request.

some average of the own wage variable. In this case, the inclusion of another variable that accounts for the mean wage of some subsample of the population that has similar characteristics to the worker's would most likely absorb some of the effect that would otherwise be (correctly) attributed to the own wage variable.

5.3 Understanding Mincer-Predicted Reference Wages

Thus far, our findings have been quite robust to different specifications and subsamples. They have also been relatively stable when using alternate definitions of comparison wages, except in the case of Mincer-predicted reference wages. In this section, we further investigate this discrepancy and argue that one of the main reasons behind the instability of the Mincer reference wage effects on subjective well-being is the indiscriminate use of exclusion restrictions that may not necessarily help accurately identify the reference wage effect. A proper instrument should be able to predict a reference wage, or define a reference group without influencing life satisfaction.³³

Table 8 displays results for various tests of the relative utility hypothesis according to other papers in the literature that construct reference wages following a Mincer approach. Each column shows the own wage and the reference wage coefficients we obtain by running a specification as close as possible to the one employed in each of the papers, but using our own data. We also report the direction and significance of the reference wage effect on well-being that the respective authors obtain in their paper using their own data.

The differences in the estimated reference wage effects, both across specifications and across samples, are striking. First, the coefficients vary significantly depending on the specification, going from -0.41 to 0.64. Thus, the discrepancies arise not only in the magnitude of the coefficients, but also in the direction of the estimated effect. Such large variation in the implied impact of reference wages on well-being is surprising given that the underlying sample is exactly the same and the only thing that changes is the exclusion restriction assumed to identify the reference wage effect. Second, note how the same (or nearly the same) specification produces very different results from those reported in the original papers for their respective samples. For instance, while Sloane and Williams (2000) find a positive and insignificant effect of reference wages on well-being when they control for variables such as hours worked, tenure, marital status, and union management experience in the Mincer equation, we obtain a negative and very significant coefficient using the same specification for our sample.

We believe that what gives rise to such disparate results is the indiscriminate use of different exclusion restrictions and the unjustified categorization of variables as belonging in either the Mincer or the well-being equation. As noted earlier, the fact that our findings are quite robust to different specifications, including those that use various constructed reference wages, suggests that something not inherently related to the estimation of the subjective well-being equation may be driving the Mincer results. Under the Mincer framework, it is up to the econometrician to decide whether a given variable belongs in one or the other equation. For example, some of the authors that follow the Mincer approach have used

³³A recent paper by Card et al. (2012) does this in a clever way by using randomized manipulation of access to information on peers' wages.

different combinations of variables including age, education, and marital status in their exclusion equations, even when these variables have shown to be both economically and statistically relevant in the subjective well-being equation.

Of course, it is also possible that the discrepancies outlined above are due to other reasons. For instance, different papers use different samples. It is possible that the estimated reference wage effects on well-being are stronger or weaker, depending on the working population. It is also entirely possible that the “tunnel effects” described in Section 2 are more prevalent in other populations. Moreover, note that, for the sake of comparison, we are restricting our estimations to the same sample of male workers with which we have worked throughout the paper. Other papers in the literature have pooled males and females and used individuals that differ in their characteristics from our sample of unionized workers employed by large, publicly-listed firms in Japan. Nonetheless, estimations using different working subsamples (not reported for brevity) produce results that are, in some cases, significantly different from the ones reported for each of the specifications in the table, which further underlines the instability of the Mincer estimates.

Summing up, the results above suggest that the use of constructed reference wages in empirical tests of the utility hypothesis produces inconsistent estimates of the effects of comparison wages on subjective well-being. Our theoretical framework demonstrates that, in the presence of several mismeasured proxies of the reference wage that is truly perceived by the worker, an instrumental variables approach may help bound the comparison wage estimate, although it does not eliminate the bias entirely. An evaluation of the various empirical constructs that the literature has previously used shows that various cell wage averages, computed both within our own dataset and from an external wage data source, perform best in the estimation of the reference wage effects compared to the self-reported reference wage measure. However, the use of Mincer-predicted reference wages obtains reference wage effects that are unstable due to multicollinearity that ad hoc exclusion restrictions typically do not solve. It is thus advised that these Mincer-predicted reference wages are employed with care.

6 Conclusions

The results in this article find strong support for the relative utility hypothesis. Using data on self-reported reference wages, we observe that individuals report lower levels of both life and job satisfaction when they perceive that their co-workers earn higher salaries. We find that the association between absolute wage effects and subjective well-being is economically stronger than that between the latter and comparison wages. Moreover, our results demonstrate that standard methods employed in the literature to estimate reference income yield inconsistent estimators of the reference income effect. In particular, we show that linear predictions of benchmark wage measures obtained by Mincer estimations perform poorly. This is mainly due to weak identifying assumptions of the comparison wage effect and a strong multicollinearity problem between predicted wages and the rest of the individual worker characteristics. In contrast, cell averages based on age, gender, and education levels and estimated using external datasets generate more reliable results.

We believe that the findings in this paper can be extended in three main directions.

First, having acknowledged the existence of important heterogeneous relative utility effects among workers, it would be relevant to better understand the source of such heterogeneity. If, for example, better informed individuals tend to exhibit stronger feelings of jealousy and a stronger negative correlation between their peers' wages and their own happiness, employers may find it beneficial to enhance the secrecy of its workers' pay information to preserve aggregate utility within the firm. Second, the disutility that workers experience from higher wages among their peers may translate into more tangible outcomes than mere answers in a survey. For instance, potential feelings of jealousy may impact worker behavior in the form of reduced teamwork and, hence, lower levels of productivity at the workplace. Alternatively, affected workers may change job search intensity, as suggested by Card et al. (2012). Third, it is plausible that workers experience loss aversion in the sense of Kahneman and Tversky (1979). Understanding workers' asymmetric responses to variations in their peers' wages may improve the design of wage setting policies and pay incentive schemes.

From a practical point of view, our findings strengthen the case to increase resources that improve the quality of surveys and data collection on job satisfaction and life happiness. Relative wage effects have obvious consequences in redistributive policies, both within a firm in the form of salary increases, as within a country in the shape of tax considerations. Through a better understanding of these potential externalities on workers, firms and governments will be able to ameliorate the design of welfare-enhancing pay schedules and fiscal programs.

Adjusted R-squared	0.074	0.069	0.069	0.069	0.069

*** p<0.01, ** p<0.05, * p<0.1. Standard errors clustered by firm in parentheses. All wage measures reported in logs. All specifications control for (log) hours worked and industry fixed effects. Specifications in bottom panel additionally account for individual worker characteristics including age, age squared, marital status, education level, managerial and blue collar dummies. Cell averages 1 and 2 calculated from our own data set and defined as (age × gender × education) and (age × gender × education × managerial tasks), respectively. Cell average 3 calculated using BSWS data and defined as (age × gender × education × managerial tasks). Mincer reference wage predicted from a standard regression of own wages on age and tenure dummies, hours worked, education level, marital status, manager, blue collar, job shock, and occupation dummies, as well as industry and year fixed effects.
