ABSTRACT

Background

The anterior cruciate ligament (ACL) is the most frequently injured ligament of the knee. Injury causes pain, effusion and inflammation leading to the inability to fully activate the thigh muscles. Regaining muscular control is essential if the individual wishes to return to pre-injury level of function and patients will invariably be referred for rehabilitation.

Objectives

To present the best evidence for effectiveness of exercise used in the rehabilitation of isolated ACL injuries in adults, on return to work and pre-injury levels of activity.

Search strategy

We searched the Cochrane Bone, Joint and Muscle Trauma Group Specialised Register (Feb 2005), the Cochrane Central Register of Controlled Trials (CENTRAL) (The Cochrane Library, Issue 1, 2005), MEDLINE (1996 to March 2005), EMBASE (1980 to March 2005), other databases and reference lists of articles.

Selection criteria

Randomised controlled trials and quasi-randomised trials testing exercise programmes designed to rehabilitate adults with isolated ACL injuries. Trials where participants were randomised to receive any combination of the following: no care, usual care, a single-exercise intervention, and multiple-exercise interventions, were included. The primary outcome measures of interest were returning to work and return to pre-injury level of activity post treatment, at six months and one year.

Data collection and analysis

Two authors independently assessed trial quality and extracted data. Study authors were contacted for additional information. Adverse effects information was collected from the trials.
Main results

Nine trials involving 391 participants were included. Only two trials, involving 76 participants, reported conservative rehabilitation and seven trials, involving 315 participants, evaluated rehabilitation following ACL reconstruction. Methodological quality scores varied considerably across the trials, with the nature of participant and assessor blinding poorly reported. Trial comparisons fell into six categories. Pooling of data was rarely possible due to lack of appropriate data as well as the wide variety in outcome measures and time points reported. Insufficient evidence was found to support the efficacy of one exercise intervention over another.

Authors’ conclusions

This review has demonstrated an absence of evidence to support one form of exercise intervention against another and the use of supplementary exercises in the management of isolated ACL injuries. Further research in the form of large scale well designed randomised controlled trials with suitable outcome measures and surveillance periods, using standardised reporting should be considered.

Plain Language Summary

Exercise for treating isolated anterior cruciate ligament injuries in adults

The anterior cruciate ligament of the knee controls movement of the lower leg bone (tibia) relative to the thigh bone (femur) and guides knee extension. Injury to this ligament is most common, especially when playing sport, through rapid stopping with a twisting movement. Injuries consist of partial or total tears in the ligament itself or where it attaches to bone. The resulting pain, fluid on the knee and inflammation limit movement and make it difficult to return to normal function and sporting activities. People are treated conservatively, or if the knee has become unstable they may need reconstruction surgery. Rehabilitation programs are an important part of treatment as return to full knee function may limit future degenerative changes in the knee. This review found no strong evidence to support one form of exercise program against another in managing anterior cruciate ligament injuries, looking at return to daily activities, work and sporting activities. Comparisons were of muscle strengthening, in weight bearing and non-weight bearing positions; at home or under supervision; and adding balance and proprioception exercises to a standard rehabilitation program.

This finding was based on nine randomised controlled trials, involving 391 mainly male people aged 15 to 49 years and followed up from 12 weeks to one year. Two trials used conservative treatment and seven trials, involving 315 participants, evaluated rehabilitation following reconstruction surgery. The small numbers of studies, non-standardised exercise programs, methods of looking at their effectiveness and reporting results contributed to the limited conclusions that could be drawn.

Background

The anterior cruciate ligament (ACL) is the most commonly injured ligament of the knee (Ageberg 2002). The incidence of isolated ACL tears is estimated to be 30 per 100,000 of population per year (Miyasaka 1991). The primary role of the ACL is to prevent an anterior translation (forward movement) of the tibia relative to the femur. It also guides the screw-home mechanism associated with knee extension, prevents hyperextension and assists in prevention of varus (bow-leg) and valgus (knock-knee) movement, especially in the extended knee. The most commonly seen mechanism of injury is through rapid deceleration with a twisting movement and hence disruption of the ACL commonly occurs in athletes. Injuries to the ACL can be defined as complete (total) or incomplete (partial) ruptures and can occur mid-substance or at the origin or insertion.

Following injury to the ACL pain, effusion and inflammation have been shown to lead to muscle inhibition (Snyder-Mackler 1994) and the inability to fully activate the thigh muscles. This, and disuse of the knee musculature, results in muscle atrophy (wasting) and can lead to joint instability. Further immobility is a consequence and a vicious spiral begins. Patients may be treated conservatively (non-operative) and those who demonstrate gross instability of the joint will often undergo reconstructive surgery.
It is proposed by some that regaining muscular control is essential if the individual wishes to return to pre-injury level of function (Henriksson 2001; Mattacola 2002) and patients will invariably be referred for rehabilitation, whether they follow a conservative or reconstructive pathway. Rehabilitation may comprise exercise (defined as “a subset of physical activity, which is volitional, planned, structured, repetitive and aimed at improvement or maintenance of any aspect of fitness or health” (Caspersen 1985)) to improve range of movement, muscle strength, balance and proprioception. Muscle-strengthening exercises can be performed in a variety of ways reflecting the types of muscle action required for normal function. These include isometric (where no movement occurs at the joint), isotonic (where movement occurs at the joint) and isokinetic (where movement occurs at the joint but the speed of movement remains constant). Isotonic and isokinetic contractions can also be performed concentrically (where the muscle shortens, for example using the muscles on the front of the thigh during standing from a seated position), or eccentrically (where the muscle is active but lengthening, for example the muscles on the front of the thigh during sitting from a standing position). Eccentric muscle activity normally occurs to control movement against gravity. Furthermore, exercise for the muscles acting on the knee may be performed as closed kinetic chain activities (weight bearing, where the foot is fixed, for example standing up from a seated position) or open kinetic chain activities (non-weight bearing, where the foot is free to move, for example straightening the knee while seated). Other modalities used during the rehabilitation phase may include cryotherapy (ice), electrotherapy (including muscle stimulation), continuous passive motion, restrictive bracing and complementary therapies such as reflexology or acupuncture.

In a previous comprehensive systematic review (Thomson 2002) the effect of rehabilitation on ACL patients was inconclusive with respect to efficacy of exercise, effectiveness of dosage, setting in which the physiotherapy-led programmes took place and level and type of supervision. Thomson 2002 also limited the trials to physiotherapy-led programmes and did not consider trials when the exercise programmes were prescribed or led by persons other than physiotherapists. That review has now been split and is being updated as a series of separate reviews that includes this current review, and one on exercise for treating isolated meniscal injuries of the knee in adults (Dixon 2005).

This review aimed to examine the effectiveness of exercise employed for the management of isolated ACL injuries in adults, whether treated conservatively or by reconstruction, on return to work and pre-injury levels of activity. For the purposes of this review, we only considered functional exercises such as gait re-education, hydrotherapy, active exercise, balance, proprioception and muscle strengthening. Trials which specifically considered use of restrictive bracing, electrotherapy or electrical stimulation, cryotherapy (ice), continuous passive motion (CPM) and complementary therapies were not considered.

O B J E C T I V E S

To present the best evidence for effectiveness of exercise used in the rehabilitation of isolated ACL injuries in adults, whether treated conservatively or by reconstruction, on return to work and pre-injury levels of activity.

The following null hypotheses were formulated. For isolated ACL injuries treated conservatively:

- there are no differences in outcome between any exercise programme versus none (control) in the rehabilitation of ACL injuries;
- there are no differences in outcome between any exercise programme versus any other exercise programme in the rehabilitation of ACL injuries.

For isolated ACL injuries treated by reconstruction:

- there are no differences in outcome between any exercise programme versus none (control) in the rehabilitation of ACL injuries;
- there are no differences in outcome between any exercise programme versus any other exercise programme in the rehabilitation of ACL injuries.

M E T H O D S

Criteria for considering studies for this review

Types of studies

Randomised controlled trials and quasi-randomised trials (e.g. randomised by date of birth or hospital record number) testing exercise programmes designed to rehabilitate adults with isolated ACL injuries (conservatively managed or reconstructed).

Types of participants

This review included trials with participants described as adults (defined as over the age of sixteen or skeletally mature) with an isolated injury to the ACL. Participant characteristics of interest included age, gender, partial or complete tear, muscle strength and level of physical ability pre-injury.

We excluded trials of interventions targeting individuals that were reported to have damage to structures in addition to the ACL. Trials that focused on participants who had underlying rheumatological, neurological, cardiovascular or congenital conditions affecting the lower limbs were also excluded from the review.
**Types of interventions**

Trials where participants were randomised to receive any combination of the following: no care, usual care, a single-exercise intervention, and multiple-exercise interventions. Trials comparing two or more interventions were also included. For the purpose of this review, exercise was considered if it took one of the following formats.

1. Muscle strengthening
   a. isometric/isotonic/isokinetic
   b. concentric/eccentric
   c. open kinetic chain/closed kinetic chain
2. Joint mobility
   a. active
   b. active assisted
   c. resisted
3. Gait re-education
4. Neuromuscular function/balance and proprioception
5. Land based/water based

The exercise interventions could take place in the home, institutional dwelling, community, gymnasium or clinic setting and could be self-supervised (for example, using exercise sheets/video), individually supervised or as part of a supervised group.

Trials that focused on the following were excluded from the review:

- electrotherapy i.e. ultrasound, Transcutaneous Electrical Nerve Stimulation (TENS), muscle stimulation;
- continuous passive motion and other forms of passive movement;
- restrictive bracing;
- cryotherapy;
- complimentary therapies such as reflexology;
- analgesics.

**Types of outcome measures**

**Primary outcomes**

The primary outcome measures of interest were returning to work and return to pre-injury level of activity post treatment, at six months and one year. To be included, trials must have reported these primary outcome measures. These could have included, but were not restricted to, outcome scales such as the Tegner Activity scale (Tegner 1985), Cincinnati Knee Rating System (Barber-Westin 1999) and Quality of Life Questionnaire for ACL deficiency (Mohtadi 1998).

**Secondary outcomes**

Secondary outcome measures could have included, but were not limited to:

- pain (residual pain or pain on movement);
- instability (as tested with arthrometry);
- swelling (for example, patella-tap test);
- range of motion of the knee;
- muscle strength (for example, isokinetic evaluation);
- muscle activation (for example, electromyography analysis (EMG);
- other complications (e.g. deep vein thrombosis (DVT), infection).

Information was sought on the level of compliance with the intervention, the magnitude and duration of effect, and adverse events associated with the exercise intervention.

**Search methods for identification of studies**

We searched the Cochrane Bone, Joint and Muscle Trauma Group Specialised Register (Feb 2005), the Cochrane Central Register of Controlled Trials (CENTRAL) (*The Cochrane Library* Issue 1, 2005), MEDLINE (1966 to March 2005), EMBASE (1980 to March 2005), PEDro - The Physiotherapy Evidence Database (http://www.pedro.fhs.usyd.edu.au/) (fast accessed March 2005), CINAHL (1982 to March 2005), AMED (1985 to March 2005), and reference lists of articles. To identify theses and unpublished trials we contacted institutions and experts in the field. No language restrictions were applied.

In MEDLINE (OVID ONLINE) the first two levels of the optimal trial search strategy (Robinson 2002) were combined with the subject specific search (Appendix 1). Search strategies are also shown for AMED (Appendix 2), CINAHL (Appendix 3), EMBASE (Appendix 4) and *The Cochrane Library* (Appendix 5).

**Data collection and analysis**

**Selecting trials for inclusion**

At least two authors, and always AT and JD, independently reviewed the title, abstract, and descriptors to identify potentially relevant trials for full review. From the full text, we selected trials that met the selection criteria for inclusion. Disagreement was resolved by consensus or third party adjudication (TH).

**Data collection**

Authors (AT and TH) independently extracted data using a customised data extraction tool tested prior to use. Disagreement was resolved by consensus or third party adjudication (JD). We contacted authors of trials if there was incomplete reporting of data.
Assessment of methodological quality

Two authors (AT and TH) independently assessed the methodological quality of each study by using a modification of the Cochrane Bone, Joint and Muscle Trauma Group quality assessment scheme. The final scoring scheme for 15 aspects of trial quality (Table 1) included items from the Cochrane Bone, Joint and Muscle Trauma Group quality assessment scheme (items denoted by ‘M’), items from the Delphi list (Verhagen 1998) (items denoted by ‘D’) and items from the Maastricht-Amsterdam consensus list for methodological quality assessment (Bellamy 1997) (items denoted by ‘MAC’). Any disagreement was resolved by consensus.

Data synthesis

Trials of ACL injuries treated conservatively were analysed and reported separately from those trials involving reconstruction. Wherever available and appropriate, we presented quantitative data for the outcomes listed in the inclusion criteria in the analysis tables. For each trial, relative risk and 95% confidence intervals were calculated for dichotomous outcomes and mean differences and 95% confidence intervals calculated for continuous outcomes (reporting mean and standard deviation or standard error of the mean).

If appropriate, we intended pooling results of comparable groups of trials using the fixed-effect model and calculating 95% confidence intervals. Heterogeneity between comparable trials would be tested using a standard chi squared test and considered statistically significant at a P value less than 0.1, after due consideration of the value of I squared. Any evidence of heterogeneity would be investigated to determine if there were obvious differences in the trials that were likely causes of the heterogeneity. If we considered that the heterogeneity was likely to have serious effects on the validity of the results then the data would not be combined. Where there was significant heterogeneity we would view the results of the random-effects model and present these when appropriate.

Sensitivity and subgroup analysis

We intended performing sensitivity analyses to investigate the effects of allocation concealment, methodological quality and intention-to-treat analysis. If the data allowed, we also planned separate outcome analyses to test the following null hypotheses:

- exercise interventions are equally effective in males and females;
- exercise interventions are equally effective irrespective of age;
- effectiveness is not dependant on the setting in which the exercise intervention is delivered;
- effectiveness is not dependant on the level or type of supervision of the exercise intervention;
- effectiveness is not dependant on the number or frequency of exercise sessions i.e. duration of rehabilitation;
- effectiveness is not dependant on the intensity of exercise interventions;
- effectiveness is not dependant on the timing of surgery.

RESULTS

Description of studies

See: Characteristics of included studies; Characteristics of excluded studies.

We identified 52 studies up to March 2005, nine of which met the inclusion criteria of the review. We excluded 42 studies, mainly because they did not report the primary outcomes of interest of this review, or they did not fit the criteria for a randomised clinical trial (see ‘Characteristics of excluded studies’ table for further details). One trial (Frosch 2001) was placed into ‘Studies awaiting assessment’ whilst awaiting correspondence from the contact author. A further two trials have been identified since March 2005, and also placed into ‘Studies awaiting assessment’ (Beynon 2005; Shaw 2005). Details of included studies, including interventions and outcomes, are presented in the ‘Characteristics of included studies’ table.

All of the included nine trials were fully reported in medical journals. Main or sole reports of the included trials were initially located from the trials identified in the original review Thomson 2002 (eight trials), or from electronic databases (one trial). All included trials were published in the English language. The publication dates for the trials included span across eight years, Beard 1994 and Tovin 1994 being the earliest. All except one, (Hooper 2001) were single centre trials. The trials were conducted in three countries, USA (five trials), UK (three trials) and Sweden (one trial).

For the purpose of this review, the primary outcome measures of interest were returning to work and return to pre-injury level of activity i.e. functional outcomes. The most commonly used primary outcome measures were the Lysholm knee score (Lysholm 1982) and Tegner activity score (Tegner 1985). The Lysholm scale is a knee specific outcome, measuring function across eight domains: limp, locking, pain, stair climbing, support, instability, swelling and squatting. An overall score out of 100 is calculated, with a score closer to 100, indicating greater functional ability. The Tegner score is an activity scale rated from zero to ten, with ten indicating participation in elite level sports, and zero indicating inability to participate in activity at any level.

Exercise as part of conservative management
Only two trials reported conservative rehabilitation (Beard 1994; Fitzgerald 2000). These two trials involved 76 participants, of those, 62 were male and 14 female. The age range of the participants was 16 to 49 years (Beard 1994) and 15 to 57 years (Fitzgerald 2000). In both trials, the number of male participants outnumbered the number of female participants.

Beard 1994 compared the effects of a supplementary proprioceptive training regime in addition to a traditional program versus a traditional program of rehabilitation alone (focussing on increasing muscle strength, predominantly using open kinetic chain exercises). The primary outcome measure of interest used in the trial was the Lysholm score at 12 weeks (immediately post-rehabilitation), and additional measures were evaluation of proprioception and knee laxity. Data was not available for the latter measure.

Fitzgerald 2000 compared the effects of a supplementary perturbation regime in addition to a standard regime versus a standard regime alone (resistive muscle strengthening, cardiovascular endurance training, agility skill training and sport specific training). The primary outcome measures of interest used in the trial were Knee Outcome Scores (Activities of Daily Living and Sports Activities Scales (Irrgang 1998) and Global Rating of Knee Function scale) measured post-treatment and at six months follow up, and a rating of successful/unsuccesful rehabilitation (return to activity with/without an episode of the knee giving way) measured at one year. Secondary measures were muscle strength and knee laxity post treatment and at six months.

**Exercise following surgical reconstruction**

Seven trials evaluated rehabilitation following ACL reconstruction, all trials used the bone-patella-bone method, carried out with arthroscopic assistance. All trials reported the use of autografts (tissue transferred from one site to another in the same individual), with the exception of one trial in which four patients were given allografts (tissue transplanted from one individual to another) (Fischer 1998). The seven trials involved 315 participants, of those, 242 were male and 73 female. Where reported, the age of the participants ranged from 15 to 48 years. In all seven trials, the male participants outnumbered the female participants.

Of the seven included trials, only one reported the mechanisms of injuries (Beard 1998), though several trials reported that their participants were physically active. Fischer 1998 excluded participants who participated in sports at collegiate/professional or elite level. Details of surgery and sports participation for the trials are given in Table 1.

Three trials (Beard 1998; Fischer 1998; Schenck 1997) compared the effects of rehabilitation at home versus supervised rehabilitation. Participants in each of the trials followed the same rehabilitation programme, with only the level of supervision differing. Primary outcome measures reported were Lysholm score (12 weeks (Fischer 1998), six months (Fischer 1998, Beard 1998) and one year (Schenck 1997), Tegner score at six months (Beard 1998) and Sickness Impact Profile (a generic measure used to evaluate the impact of disease on both physical and emotional functioning) at one year (Schenck 1997). Secondary measures were evaluation of muscle strength, knee range of movement and knee laxity at six months post-reconstruction.

Bynum 1995 and Hooper 2001 compared closed kinetic chain exercise programme versus open kinetic chain programmes. The primary outcome measures of interest used in the trials were Lysholm and Tegner scores measured at one year (Bynum 1995) and Hughston Knee Functional score measured at six weeks (Hooper 2001). Secondary measures reported were severity of patellofemoral pain at one year, knee laxity and Lachman test (clinical test of instability) at one year (Bynum 1995).

Mikkelsen 2000 compared the effect of a closed kinetic chain program versus a combined closed and open kinetic chain program. Both groups followed an identical program for six months but with the open chain group performing additional exercises from week five (post-reconstruction). The primary outcome measure of interest was reported as return to pre-injury level of sport measured at 31 months after surgery. Secondary measures were knee laxity and muscle strength, measured at six months after surgery.

Tovin 1994 compared a land based rehabilitation program with a water based program. Exercises in both programs were identical. The primary outcome measure of interest was the Lysholm score, and the secondary measure was muscle strength. Both outcomes were measured at the end of the eight week program.

Risk of bias in included studies

Methodological quality scores, on our quality assessment scheme for 15 aspects of trial quality (Table 2), varied considerably across the trials, with Beard 1994 and Beard 1998 being the highest scoring trials, though no trials scored maximally.

Table 2. Quality assessment items and possible scores  (Continued)

1 = adequate.
0 = not defined, not adequate.

M-L. Was the surveillance active, and of clinically appropriate duration (i.e. at least 12 months)?
2 = active surveillance and appropriate duration (12 months follow up or more).
1 = active surveillance, but inadequate duration (6-12 months follow up).
0 = surveillance not active or not defined (0-6 months).

D7. Were point estimates and measures of variability presented for the primary outcome measures?
2 = yes.
1 = point estimates, but no measures of variability presented.
0 = vague descriptions.

MAC-1. Was the compliance rate in each group likely to cause bias?
2 = compliance well described and accounted for in analysis.
1 = compliance well described but differences between groups not accounted for in analysis.
0 = compliance unclear.

MAC-2. Was there a description of adverse effects of the intervention(s)?
2 = well described.
1 = poorly described.
0 = not described.

Exercise as part of conservative management

Beard 1994 reported adequate random allocation of participants (computer generated allocation) and treatment allocation was judged as concealed. In Fitzgerald 2000, allocation of participants was generated by computer, but there was insufficient information to judge whether allocation was concealed. Beard 1994 described blinding of both assessors and participants. Both trials scored highly in the description of inclusion/exclusion criteria, definitions of interventions and outcome measures and appropriateness of outcome measures. It was not felt that length of surveillance was adequate for either trial (Beard 1994 12 weeks, and Fitzgerald 2000 five weeks). Neither trial scored highly in the description of compliance or adverse events. Details of the methods of randomisation, extent of assessor and participant blinding, the possibility of intention-to-treat analysis and associated loss to follow up for individual trials are provided in Table 3 and the ‘Characteristics of included studies’ table.

Exercise following surgical reconstruction

Only five of the seven trials reported a method of randomisation, with only Beard 1998 providing adequate details of these methods. Allocation was judged to be concealed in one trial (Beard 1998), uncertain in the remaining six trials (Bynum 1995; Fischer 1998; Hooper 2001; Mikkelsen 2000; Schenck 1997; Tovin 1994). With the unavoidably difficult task of blinding the treatment providers to group allocation, it would seem essential to blind assessors. Only two trials (Beard 1998; Bynum 1995) stated the assessors were fully blinded, though one trial (Schenck 1997) reported the use of an independent assessor. With the exception of Beard 1998, there was insufficient information to confirm that intention-to-treat analysis had been carried out.

All trials provided descriptions of the inclusion and exclusion criteria, and definitions of interventions and outcome measures. Adequate surveillance (Table 2 ‘Quality assessment items and possible scores’ item M-L) was only carried out in two trials; Bynum 1995 average of 19 months and Mikkelsen 2000 average of 31 months for return to pre-injury level of sport. Reporting of adverse events and compliance was poor for all seven trials. Details of the methods of randomisation, extent of assessor and participant blinding, the possibility of intention-to-treat analysis and associated loss to follow up for individual trials are provided in Table 4 and the ‘Characteristics of included studies’ table.

**Effects of interventions**

No trials were included that reported the effect of exercise versus no exercise.

**Exercise as part of conservative management**

**Supplementary proprioceptive training versus traditional regime (Comparison 01)**

In Beard 1994 (50 participants) there was no significant difference at twelve weeks post-treatment, between the traditional regime with supplementary proprioceptive training and a traditional regime alone in improving functional status, as measured by the Lysholm score (WMD 7.00, 95% confidence interval (CI) -4.01 to 18.01) (see Graph 01.01).

**Supplementary perturbation training versus standard regime (Comparison 02)**

In a small study by Fitzgerald 2000 (26 participants), there was no significant difference post-treatment or at the six month follow-up assessment in Knee Outcome Scores (Activities of Daily Living, Sports Activity scores, Global Rating of Knee Function) between the standard regime supplemented by perturbation training versus the standard regime alone (see Graph 02.01). However, return to full activity at six months was more common for the group receiving supplementary perturbation training (RR 1.83, 95% CI 1.06 to 3.18) (see Graph 02.02), although the definition of “successful outcome” for return to full activity was not clear and the methods for acquiring this data not described in the text. There was no difference between the groups for other secondary outcome measures: isometric quadriceps strength measured post-treatment and at six months and knee laxity measured post-treatment (see Graphs 02.03 and 02.04).

**Exercise following surgical reconstruction**

**Home based versus supervised rehabilitation (Comparison 03)**

We identified one outcome measure (Lysholm score) and time point (six months) that was addressed by more than one trial and allowed pooling of data (Beard 1998; Fischer 1998). These trials involving a total of 80 participants compared home based versus supervised rehabilitation. There was no evidence of a difference between the two groups (WMD 1.46, 95% CI -3.19 to 6.10) (see Graph 03.01). Additional non-pooled data did not demonstrate a difference in Lysholm score at twelve weeks (Fischer 1998) or in Tegner score (per cent change) at six months (Beard 1998). There was no difference between the groups for other secondary outcome measures: muscle strength (torque ratio) measured at three and six months (Beard 1998), knee laxity measured at six months (Beard 1998) or knee range of movement (ROM) measured at 6 and 12 weeks (Fischer 1998). Knee ROM at 18 and 24 weeks showed a difference between the groups (18 weeks: WMD -6.00, 95% CI -11.76 to -0.24 and 24 weeks: WMD -8.00, 95% CI -12.92 to -3.08) (see Graph 03.05), favouring home based exercise (Fischer 1998). It is not known at what point in the range of movement these improvements were deemed to have been made i.e. resolving lack of extension or improving flexion. The average differences between the groups of six to eight degrees may not be a clinically important change as the precision of measuring joint range with goniometers and visual estimation is limited to similar values (Watkins 1991). Furthermore, the data used for the purposes of this review were taken from visual estimates of figures in the original paper. Although the outcome measures reported by Fischer 1998 were appropriate, the overall methodological reporting of this trial was poor.

**Closed kinetic chain versus open kinetic chain rehabilitation (Comparison 04)**

Trials investigating closed kinetic chain versus open kinetic chain rehabilitation did not demonstrate any differences between the groups in knee function: Hughston Clinic Functional Score at six weeks post-surgery (Hooper 2001) (WMD 0.00, 95% CI -9.34 to 9.34) (see Graph 04.03) and patellofemoral pain severe enough to restrict activity at one year (Bynum 1995) (RR 1.34, 95% CI 0.59 to 3.07) (see Graph 04.04). There was no difference between the groups for the secondary outcome measure, negative Lachman test measured at one year (Bynum 1995) (RR 0.93, 95% CI 0.80 to 1.09) (see Graph 04.06). However, Bynum 1995 did not report the levels at which participants were restricted from activity, nor the degree of patellofemoral pain causing restriction to activity.

Closed kinetic chain versus closed and open kinetic chain rehabilitation (Comparison 05)

In a trial of 44 participants, return to pre-injury level of sport by 31 months after surgery was statistically significantly more common in the closed and open kinetic chain rehabilitation program compared to the closed chain only program (Mikkelsen 2000) (RR 0.42, 95% CI 0.18 to 0.98) (see Graph 05.01). There was no difference between the groups for the secondary outcome measures: knee laxity and isokinetic quadriceps strength measured at six months post-surgery (see Graphs 05.02 and 05.03).

Land based versus water based rehabilitation (Comparison 06)

In a small study by Tovin 1994 (19 participants) comparing land and water based rehabilitation, a higher Lysholm score, measured at eight weeks, was observed in the water based group (WMD 9.80, 95% CI 1.29 to 18.31) (see Graph 06.01). There was no difference between groups in muscle strength measured at eight weeks, with the exception of peak isokinetic torque 90°/second - flexion which favoured land based rehabilitation (WMD -14.70, 95% CI -25.89 to -3.51) (see Graph 06.02).

Subgroup analysis

The effect of the setting and level of supervision on the effectiveness of exercise programmes were considered in comparison 03 (home based versus supervised rehabilitation) and comparison 06 (land versus water based rehabilitation) and reported above. However, due to the limitations of the data available, we were unable to perform separate subgroup analyses to test the following null hypotheses:

- exercise interventions are equally effective in males and females;
- exercise interventions are equally effective irrespective of age;
- effectiveness is not dependant on the number or frequency of exercise sessions i.e. duration of rehabilitation;
- effectiveness is not dependant on the intensity of exercise interventions;
- effectiveness is not dependant on the timing of surgery.

DISCUSSION

This review aimed to examine the effectiveness of exercise employed for the management of isolated ACL injuries in adults, whether treated conservatively or by reconstruction, on return to work and pre-injury levels of activity. For the purposes of this review, we only considered exercises such as gait re-education, hydrotherapy, active exercise, balance, proprioception and muscle strengthening. Trials which specifically considered use of restrictive bracing, electrotherapy or electrical stimulation, cryotherapy (ice), continuous passive motion (CPM) and complementary therapies were not considered.

In all, the search to March 2005 resulted in the identification of 52 trials. Nine trials, involving 391 participants (304 male and 87 female) met the inclusion criteria of the review. Only two trials, involving 76 participants, reported conservative (non-operative) rehabilitation and seven trials, involving 315 participants, evaluated rehabilitation following ACL reconstruction.

Methodological quality scores varied considerably across the trials, with the participant and assessor blinding poorly reported. Sample sizes of the included trials ranged from 20 to 97 participants raising questions as to the power of individual trials. Adequate surveillance (at least one year) was only observed in two trials, Bynum 1995 average of 19 months (Lysholm score) and Mikkelsen 2000 average of 31 months (return to pre-injury levels of sport). The nature of the intervention - exercise - makes it virtually impossible for trials to be blinded to care providers and participants, although blinding of assessors would be possible.

Most comparisons were of usual care only versus usual care with supplementary exercise. No trials reported the use of a control group (participants receiving no treatment). However, the nature of injury to the ACL is typically suggestive of individuals who participate in sporting activities, and who may be reluctant to forgo any form of rehabilitation with the perception that this may further delay a return to their normal activities.

For the purposes of this review, the primary outcome measures of interest were: returning to work and return to pre-injury level of activity post treatment, at six months and one year. The trials included in this review reported on these using a variety of measures including the Tegner Activity scale (Tegner 1985), Lysholm score, Knee Outcome Score Activities of Daily Living (Irrgang 1998) and return to pre-injury level of activity. Though appropriate outcome measures, there was inconsistency between trials on the surveillance periods, ranging from five weeks (Fitzgerald 2000) to 31 months post-treatment (Mikkelsen 2000). It is reported that
patients with ACL reconstruction may not regain normal muscle strength at the knee until 10 to 22 months following surgery during walking and even longer during running (DeVita 1998), and similarly restoration of proprioceptive function in the knee may take up to 18 months (Iwasa 2000). Therefore the time points of six months and one year selected for this review maybe insufficient despite the introduction of accelerated programmes of four to six months duration.

Secondary outcome measures reported included; knee range of movement, muscle strength (isometric and various speeds of isokinetic), knee laxity, proprioceptive ability and gait analysis.

The most important feared consequence of dynamic exercise or testing at high intensity is damage to a reconstructed or partially ruptured anterior cruciate ligament or further damage to the structures around the knee joint. This factor places a limitation on the aggressiveness of the clinical outcome measures to assess success efficacy of interventions. For example, using Noyes Hop Test (Noyes 1991) as a measure in the early stages post-ACL reconstruction or acute stages of a partial or complete rupture treated conservatively would be deemed inappropriate, though clinically it would be useful in the later stages of rehabilitation and prior to returning to sport.

The International Classification of Functioning, Disability and Health (ICF) was endorsed by the World Health Organization in 2001 (WHO 2001) as a conceptual framework for the description of health and health related states. The multi-dimensional concepts relate to disability and functioning and the consequences of health conditions. The ICF assists in scientific research by providing a framework or structure for research and for making results of research comparable.

The wide variety of outcome measures used in trials included in this review supports the need for a general agreement about outcome measures used in trials of exercise based interventions. International consensus on a core set of outcome measures and surveillance periods to determine the effect of exercise therapy, for example, knee outcome scales, muscle strength, joint mobility and knee laxity, should be considered.

In this review comparisons fell into six categories. Pooling of data was impeded by lack of appropriate data as well as the wide variety of outcome measures and surveillance periods. This was compounded further by differences in test protocols and test equipment in measuring knee outcome scales, muscle strength, range of movement and joint laxity. The Lysholm score was the only measure applied in more than one trial that compared the same exercise interventions. Due to these and other methodological and reporting factors the authors of this review conclude that there is insufficient evidence to support the efficacy of one exercise intervention over another in the conservative or post-reconstruction rehabilitation of adults with isolated anterior cruciate ligament injuries on return to work or pre-injury levels of activity.

AU THORS’ CONCLUSIONS

Implications for practice

Conventionally, clinicians treating ACL injuries aim to restore function and assist patients in a return to pre-injury levels of activity, by ‘prescribing’ an exercise program to increase joint mobility, muscle strength, proprioceptive awareness and general fitness and many such interventions have been reported.

Given that joint dysfunction has a tendency to lead to the development of degenerative joint disease, a priority for clinicians should be to encourage full restoration of function using an accepted efficacious programme of rehabilitation. This review has demonstrated an absence of evidence to support one form of exercise intervention against another in the management of isolated ACL injuries. Results of the long term effect of exercise are not available due to the inadequate length of surveillance of trials.

Implications for research

This review has demonstrated an absence of evidence to support one form of exercise intervention against another in the management of isolated ACL injuries. Further research in the form of large scale well designed randomised controlled trials with suitable outcome measures and surveillance periods, using standardised reporting should be considered. International consensus on a core set of outcome measures and surveillance periods to determine the effect of exercise therapy for example; knee outcome scales, muscle strength, joint mobility and knee laxity should be considered.

ACKNOWLEDGEMENTS

We would like to thank the following for their helpful editorial comments on the protocol and review: A/Prof Peter Herbison, Prof Rajan Madhok, Dr Janet Wale, Prof Sallie Lamb and Prof David Baxter. We would like to thank Lesley Gillespie for her help with developing the search strategy and Lindsay Thomson, Helen Handoll, Aileen Cunningham and Treena Shaw for their work on the previous review (Thomson 2002). We would like to thank Lesley Gillespie, Jane Dennis and Anette Bluemle for their invaluable help with the translations and Jayne Elms for her help with management of the review.

**Beard 1994**

| Methods | Method of randomisation: minimisation computer program. Stratification variables included gender, time since injury, frequency of sport participation and frequency of giving way.  
Assessor blinding: single examiner, blinded to group allocation.  
Participant blinding: patients unaware of differences in regimes.  
Loss to follow up: 7 patients  
Intention-to-treat analysis: yes, though data not available |
|---|---|
| Participants | Location: Nuffield Orthopaedic Hospital, Oxford, UK  
Participants: 50; 42 male, 8 female  
Age: mean 25 (range 16 to 49)  
Sports injury: no data.  
Inclusion: aged between 16 and 50 years, having an arthroscopically confirmed complete rupture of the anterior cruciate ligament  
Exclusion: complex meniscal tears, grade III collateral ligament damage, chondral damage, symptoms in the other knee or hips, ankles or feet, previous formal rehabilitation or operation for ACL deficiency, greater than 36 months post injury, or underlying neurological disease. Level of instability and general function subjectively worsened following diagnostic arthroscopy. 3 weeks post-arthroscopy: loss of full range of motion, unable to mobilise without walking aids, joint effusion or pain. |
| Interventions | First three weeks following arthroscopy all patients performed range of movement and gentle isometric/isotonic quadriceps and hamstring exercises.  
Attendance commenced three weeks post arthroscopy. Twice weekly attendance for 12 weeks, 1 hour session (class) in physiotherapy department and daily home exercise plan (1 hour).  
(1) Traditional regime based on UK rehabilitation protocols.  
Strength: open kinetic chain exercises, graduated weight-resisted exercises, slight emphasis on hamstrings.  
Progression by increasing weight resistance.  
(2) Proprioceptive regime based on existing protocols and new adaptations. Facilitation of rapid contraction of hamstrings, improving dynamic stability. Progression by decreasing stability of starting position, increasing repetitions, removing visual feedback. Closed kinetic chain and functional exercises.  
Assigned: 25/25  
Assessed: 20 traditional, 23 proprioception |
| Outcomes | Length of follow up: 12 weeks  
Outcomes assessed at start (3 weeks post-arthroscopy) and 12 weeks (end of regime)  
Knee function: Lysholm score.  
Proprioception measured using Vicon Interfaced Knee Displacement Equipment.  
Knee laxity measured with KT-1000 arthrometer.  
Compliance: mean number of attendances in traditional group was 12 (SD 4), and proprioceptive group 14 (SD 6). No attempt was made to evaluate the compliance with the home exercise plan. |

**Beard 1998**

**Methods**
Method of randomisation: minimisation computer program. Stratification variables included gender, sports level, sports frequency, knee stability (frequency of giving way) and time since injury.
Assessor blinding: yes
Participant blinding: yes
Intention-to-treat analysis: included but did not alter the significance of the findings (data not presented).
Loss to follow up: 5

**Participants**
Location: Nuffield Orthopaedic Hospital, Oxford, UK
Participants: 31 before losses. Of the 26 who completed the study, 21 male and 5 female.
Age: median 28 (range 20-46). Mean age of supervised group 29, of home group 27.
Sports injury: over 86% of participants sustained their injury during sport activities
Inclusion: chronic ACL deficiency resulting in ACL reconstruction using the Bone-patella-bone (mid 1/3) technique.
Exclusion: no details

**Interventions**
All patients seen in first week after discharge, randomised. For the first 4-6 weeks all patients completed same program, twice weekly supervised sessions in first two weeks, then once weekly thereafter. The decision to initiate group exercise was made by the treating therapist and based on the clinical status of the patient with respect to class exercises of known difficulty. A flexible 2 week window for initiation of the supervised sessions was chosen because the trial was designed to be pragmatic and reflect standard clinical practice.
(1) Home exercises or alternative private facilities. Attended the rehabilitation department only for assessment, education, modification and progression.
(2) Supervised twice weekly exercises, in a class setting in addition to the home program followed in (1) above. Discharged from the class between 16 and 18 weeks post-operatively. Patients completed at least 12 weeks under supervision.
Assigned: 13/13
Assessed: 13/13

**Outcomes**
Length of follow up: 6 months
Outcomes assessed at 2 weeks prior to surgery, 3 and 6 months post-surgery.
Knee function: Lysholm and modified Tegner scores.
International Knee Documentation Committee knee assessment form.
Visual analogue scales for sports participation and activities of daily living.
Muscle strength measure by dynamometry.
Knee laxity measured with a KT-1000 arthrometer.
Compliance: 5 patients lost to follow up. Patients did not complete compliance evaluation forms. Group (2) participants attended a median of 16 sessions (range 10 - 22).
Rehabilitation program consisted of range of movement exercises, isometric (static) muscle contractions, graduated weight bearing, open and closed chain exercises for quadriceps and hamstrings, progression to proprioceptive and balance re-education, functional activities and preparation to return to sports at six months.

### Bynum 1995

**Methods**

Method of randomisation: sealed and numbered envelopes, pre-determined by computer generated table of random numbers.

- Assessor blinding: yes
- Participant blinding: no details
- Intention-to-treat analysis: not mentioned.
- Loss to follow up: Fifteen in total (3 patients did not complete the rehabilitation, and 12 failed to return for follow up).

**Participants**

- Location: Naval Medical Centre, California, USA
- Participants: 100: 97 completed the rehabilitation programme (88 male, 9 female).
- Age: mean age 26, range 18-48
- Sports injury: indication that patients participated in sports at recreational level, but not whether sport was the cause of injury.
- Inclusion: minimum age of 18, isolated ACL injury, normal contralateral knee, rigid graft fixation following arthroscopically assisted Bone-Patella-Bone middle 1/3 autograft.
- Exclusion: not stated

**Interventions**

Following surgery, all patients were placed in a long leg hinged knee brace allowing 0 - 90° of motion. Continuous passive movement from 0 - 60° continued for 12 hours daily until discharge. Rehabilitation began on day one with passive, active assisted and active movement. Partial weight bearing was permitted, with progression to full weight bearing. At twelve months, patients returned to unrestricted sports.

1. Closed kinetic chain protocol using Sport Cord:
   - week 6: stationary cycling;
   - week 8: progressive resistance training with Sport Cord and jogging;
   - week 12: jumping;
   - week 24: running and sport-specific rehabilitation.

2. Open kinetic chain protocol:
   - weeks 0 - 3: isometric and isotonic exercises;
   - week 6: low resistance stationary cycling; week 8: isokinetic hamstrings;
   - week 12: unrestricted isotonics;
   - week 24: unrestricted progressive resistance training;
   - 7 - 8 months: running and sport specific rehabilitation.

- Assigned: 50/47
- Assessed: 44/41 for subjective and objective measurements at 12 months follow up.

Fischer 1998

Methods

Method of randomisation: not stated
Assessor blinding: not stated
Participant blinding: not possible
Intention-to-treat analysis: not mentioned.
Loss to follow-up: 1

Participants

Location: Minneapolis Sports Medicine Centre, Minneapolis, USA.
Participants: 54, 28 male, 26 female.
Age: mean age 30, range 15 to 44.
Sports injury: no data available.
Inclusion: over the age 15, minimum period of 6 weeks between injury and surgery, confirmed isolated complete ACL rupture and able to give informed consent.
Exclusion: previous repair or reconstruction of knee ligaments, professional, collegiate or elite athletes, and any complicating medical conditions.

Interventions

All patients were given a home exercise program divided into four phases:
1 restoration of range of motion;
2 functional strengthening;
3 advanced functional strengthening;
4 speed and agility training.
All patients returned for follow up at three days post-operatively.
 Patients were allocated into one of two groups.
(1) Home group - prescribed six physical therapy visits (weeks 1, 2, 3, 4, 6, and 12). Average of 5 visits, range 3 - 7.
(2) Clinic group - 24 physical therapy appointments in first 6 months. Average 19.9 visits, range 10-28.
Assigned: 27/27
Assessed: 27/26

Hooper 2001

Methods
Method of randomisation: block randomisation (randomised blocks of four subjects at a time to ensure that nearly equal numbers were assigned to each group).
Assessor blinding: unclear
Participant blinding: not stated
Intention-to-treat analysis: not mentioned
Loss to follow up: 6

Participants
Location: Department of Health Sciences, University of East London, UK.
Participants: 43; of 37, 29 male and 8 female.
Age: no data available.
Sports injury: no data available.
Inclusion: ACL reconstruction by either a) arthroscopically assisted Bone-Patella-Bone middle 1/3 autograft or b) ligamentous augmentation device technique. Patient able to flex knee greater than 90° and walk unaided.
Exclusion: history of pathological problems in the contralateral limb, history to the PCL in the injured limb, any post-operative complications.

Interventions
Patients all underwent gait analysis at 2 weeks post-operatively and then allocated into one of two groups undertaking rehabilitation 3 times per week, for four weeks.
(1) Closed kinetic chain group - unilateral resistance hip/knee extensor training (3 sets, 20 repetitions, 90°-0°), stationary cycling, balance and proprioceptive training.
(2) Open kinetic chain (OKC) group - hip and knee extension with weights/machines (velocity controlled 60°/s concentric and 30°/s eccentric), stationary cycling, balance and proprioceptive training.
Assigned: 18/19
Assessed: 18/19 with exception of stair ascent/descent with two drop-outs (not stated which group).

Outcomes
Length of follow up: 4 weeks
Outcomes assessed at 2 weeks and 6 weeks post-operatively.
Hughston Clinic (Knee) visual analogue scale (6 weeks).
Gait analysis (2 and 6 weeks).
Stair ascent/descent (? only at 6 weeks).
Compliance: not stated.

#### Mikkelsen 2000

**Methods**
- Method of randomisation: unclear
- Assessor blinding: unclear
- Participant blinding: unlikely.
- Intention-to-treat analysis: not mentioned.
- Loss to follow up: none

**Participants**
- Location: Karolinska Hospital, Stockholm, Sweden.
- Participants: 44, 34 males, 10 females
- Age: range 18-40
- Sports injury: all patients (except one) were athletes.
- Inclusion: chronic ACL injury resulting in reconstruction.
- Exclusion: previous serious knee injury, concomitant other injury affecting rehabilitation, unhealthy contralateral limb.

**Interventions**
- Description: all patients underwent the same rehabilitation protocol for the first five weeks (range of motion, flexibility training, proprioceptive and balance training, closed kinetic chain exercises and hamstring training).
- At week 5, patients were randomly assigned into one of two groups.
  2. Isokinetic group - standard protocol plus open kinetic chain isokinetic quadriceps (concentric and eccentric) training until 6 months after surgery.
- Assigned: 22/22
- Assessed: 22/22

**Outcomes**
- Length of follow up: Mean 31.0 ± 9.7 months (questionnaire).
- Outcomes assessed pre-operatively and at 6 months.
- Function: return to sports questionnaire.
- Knee laxity measured with KT-1000 arthrometer.
- Isokinetic muscle torque measured with dynamometry.
- Compliance: not stated.

**Notes**
- POST-RECONSTRUCTION
  All patients underwent arthroscopically assisted Bone-Patella-Bone middle 1/3 autograft.

#### Risk of bias

</table>
Methods

Method of randomisation: lottery numbers 1-100. Odd and even split into two groups.
Assessor blinding: independent observer blinded to allocation.
Participant blinding: not possible.
Intention-to-treat analysis: not mentioned.
Loss to follow up: none.

Participants

Location: University of Texas, Texas, USA.
Participants: 37, 28 male and 9 female.
Age: mean 24.1 years, range 18 to 32 years.
Sports injury: no details.
Inclusion: aged over 18 years, torn ACL and knee instability resulting in reconstruction.
Exclusion: no other details.

Interventions

All patients were given pre-operative education and followed similar goals - obtaining full range of motion, normal gait, and quadriceps/hamstrings strengthening.
(1) Clinic group - 3 visits per week over 6 weeks. Averaged 14.2 visits (range 6-40). Average cost $930.
(2) Home group - individual functional exercise programs monitored via clinic visits by a physical therapist (determined by visits at 3 and 10 days post-operatively). Averaged 2.85 visits (range 0 - 6). Average cost $225.
Assigned: 15/22
Assessed: 15/22

Outcomes

Length of follow up: 1 year.
Outcomes assessed pre-operatively, 3 months post-operatively and 1 year post-operatively.
Lysholm knee rating scale.
Sickness Impact Profile Questionnaire.
Knee range of motion.
Pain: visual analogue scale.
Single leg hop test.
Knee laxity measured with KT-1000 arthrometer.
Compliance: measured at 1 year post-operatively.

Notes

POST-RECONSTRUCTION
Reconstruction: arthroscopically assisted Bone-Patella-Bone middle 1/3 autograft

Methods
Method of randomisation: coin toss. Patients allocated in pairs into opposite groups.
Assessor blinding: some blinding occurred.
Participant blinding: not possible.
Intention-to-treat analysis: not mentioned.
Loss to follow up: 1

Participants
Location: Piedmont Hospital, Atlanta, USA.
Participants: 20, 14 male and 6 female.
Age: mean age 29.0 (SD 7.8), range 16 to 44.
Sports injury: no details.
Inclusion: ACL reconstruction using Bone-Patella-Bone autograft.
Exclusion: prior ACL surgery to either knee or meniscal repair at time of surgery.

Interventions
All patients followed the same rehabilitation program in the first post-operative group (range of motion exercises, stretches, strengthening exercises and gait retraining). In weeks 2 to 8, patients were assigned to one of two groups, and sessions were 3 times per week.
(1) Land based group - cycling, gait training, side steps and step ups, hip strengthening, and hamstring strengthening (closed chain).
(2) Pool based group - as for land based group, but within the pool (closed chain).
Assigned: 10/10
Assessed: 9/10

Outcomes
Length of follow up: 8 weeks.
Outcomes assessed at various points (see below).
Lysholm Score and functional questionnaire (8 weeks).
Joint laxity measured with KT-1000 arthrometer (pre-op and 8 weeks).
Isometric and isokinetic peak knee torques measured with dynamometry (8 weeks).
Passive range of motion (2, 4, 6 and 8 weeks).
Thigh girth (pre-op and 2, 4, 6 and 8 weeks).
Compliance: not stated.

WHAT'S NEW

Last assessed as up-to-date: 7 June 2005.

8 September 2008 Amended Converted to new review format.

HISTORY

Protocol first published: Issue 2, 2005
Review first published: Issue 4, 2005

18 May 2006 Amended In this minor update (published in Issue 3, 2006), format changes were undertaken to comply with the Cochrane Style Guide (May 2006).

24 August 2005 Amended In a previous comprehensive systematic review (Thomson 2002) the effect of rehabilitation on ACL patients was inconclusive with respect to efficacy of exercise, effectiveness of dosage, setting in which the physiotherapy-led programmes took place and level and type of supervision. That review also limited the trials to physiotherapy-led programmes and did not consider trials when the exercise programmes were prescribed or led by persons other than physiotherapists. That review has now been split and is being updated as a series of separate reviews that includes this current review, and “Exercise for treating isolated meniscal injuries of the knee in adults” (Dixon 2005).
CONTRIBUTIONS OF AUTHORS

AH Trees, the guarantor for this review, conceived, designed and wrote the protocol, assisted in the development of the search strategy, performed the identification of studies, data extraction, methodological assessment, analysed the results, and wrote and entered the review into RevMan.

TE Howe conceived, designed and wrote the protocol and developed the quality assessment scheme, performed data extraction, methodological assessment, analysed the results and wrote the review.

J Dixon conceived and designed the protocol, and assisted with the search strategy development, identified studies for the review, performed data extraction and commented on drafts of the review.

L White commented on drafts of the protocol and review and assisted in identification of studies for the review.
