Abstract

A key concern about population aging is the decline in the size of the economically active population. Working longer is a potential remedy. However, little is known about the length of working life and how it relates to macroeconomic conditions. We use the US Health and Retirement Study for 1992-2011 and multistate life tables to analyze working life expectancy at age 50 and study the impact of the Great Recession in 2007-2009. Despite declines of 1-2 years following the recession, in 2008-2011 American men aged 50 still spent 13 years, or two-fifths of their remaining life, working; while American women of the same age spent 11 years, or one-third of their remaining life, in employment. Although educational differences in working life expectancy have been stable over the past 20 years, racial differences started changing after the onset of the Great Recession. Our results show that while Americans generally work longer than people in other countries, there is considerable sub-population heterogeneity. We also find that the time trends are fluctuating, which may prove troublesome as the population ages. Policies targeting the weakest performing groups may be needed to increase the total population trends.

Introduction

Population aging is one of the major global challenges of the 21st century. In the coming decades, the number of people aged 65 and older will grow substantially in the vast majority of countries (United Nations 2015). The US Census Bureau predicts an increase in the proportion of the population aged 65 and older, from 15% in 2014 to 24% in 2060 (Colby and Ortman 2015). The main concerns that arise in discussions about population aging in the US and elsewhere are related to the long-term sustainability of social security systems, as the proportion of the population who remain economically active is projected to decrease. Yet because the length of working life is of critical importance to the long-term sustainability of these systems, policies aimed at encouraging people to work longer are being implemented. In the US, the Social Security retirement age has been increased from age 65 to 66 for individuals born in 1943-1954, and will increase further for cohorts born in 1955 and later (Behagel and Blau 2012).

However, in addition to policies, macroeconomic conditions likely play a key role in determining how long people work. In 2007-2009, the US was hit by the “Great Recession”, the most severe economic downturn the country had experienced since World War II (Goodman and Mance 2011). In the years following the recession, the unemployment rate more than doubled, from 4.6% in 2007 to 9.6% in 2010 (Bureau of Labor Statistics 2016). While it is likely that this shock had an impact on the average length of working life in the US, both the direction and magnitude of the effects are unknown, as there is evidence of trends toward both decreasing employment and postponed retirement. Moreover, nothing is known about the heterogeneity of the effects of the Great Recession on the average length of working life across sub-populations with varying degrees of attachment to the labor market and vulnerability to labor market fluctuations.

Most of the existing research on the length of working life in the US, or working life expectancy (WLE), has focused on a single period (see Skoog and Ciecka 2009 for an overview of some of the literature). An exception is Skoog and Ciecka (2010), who analyzed data from the Current Population Survey (CPS). They found that between 1970 and 2003, WLE measured at age 20 changed little among men, but increased somewhat among women. Differentials in WLE by gender, race/ethnicity, and education have received more attention in the literature than the overall trends. Generally, males have a higher WLE than females (e.g., Warner et al. 2010). Using period working life tables, Smith (1986) found that the differences between whites and non-whites are relatively small among women, and are larger among men. Applying a similar methodology in their analysis of 1990-2000 CPS data, Millimet et al. (2003) came to the same conclusion, noting that the differences between white and non-white males diminish with age. Hayward and Grady (1990) used cohort data to compare black and non-black males, and found only a small gap in WLE, while the difference between white and black males reported by Hayward et al. (1996) is relatively large. Several of these studies have also uncovered differentials that suggest that people who are better educated work longer than people with less education (Smith 1986; Hayward and Grady 1990; Millimet et al. 2003).

In this paper, we use 20 years of data from the Health and Retirement Study (HRS) to calculate period working life tables for five-year intervals. We use these tables to analyze recent developments in WLE at age 50 in the US, with a focus on the changes in WLE following the Great Recession. As the previous literature has observed that WLE levels differ considerably across sub-populations defined by sex, education, and race/ethnicity,

we provide detailed results on the trends among these populations. Moreover, we present a methodology that allows us to match our period working life tables with external life tables. Our study contributes to the literature in several ways. First, the topic of how economic downturns affect WLE has previously received little attention. Second, we present findings for whites, blacks, and Hispanics; whereas most existing studies have compared whites and non-whites. Moreover, we assess the interaction of race/ethnicity and education. Third, unlike in the previous literature, our approach to matching the period working life tables with external life tables does not assume constant mortality across labor force states and educational levels.

Analyzing trends in WLE might yield valuable insights, especially in the context of the 2007-2009 recession. Expectations regarding the impact of the Great Recession on older age groups are not clear-cut, and the overall effect of the drastic increase in unemployment mentioned above is uncertain. While Engemann and Wall (2009) reported that employment increased when measured by the number of workers aged 55 and older, both Farber (2011) and Cahill et al. (2015) found sharp increases in the unemployment rates of older workers. Moreover, Coile and Levine (2011) found that during the recession unemployed workers had a higher probability of retiring than employed workers. On the other hand, Hurd and Rohwedder (2010) presented findings that suggest that the recession may have led to the postponement of retirement due to the negative effects of the downturn on wealth, and especially on home equity (also see Ondrich and Falevich 2016). Thus, the net impact of the recession on WLE at older ages remains unclear, and it is hard to predict whether the crisis has led to an increase or a decrease in WLE.

While the overall impact of the recession on older individuals is uncertain, the effects can be expected to differ by gender, education, and race/ethnicity. If we look at research on the impact of the recession on (un)employment across the population, we see that there is a general consensus that men were more affected than women, the less educated were more affected than the better educated, and whites were less affected than blacks (Engemann and Wall 2009). Given that before the crisis males had a higher WLE than females, we might expect to find that the gap between men and women narrowed. In contrast, there is evidence that the educational differences in WLE levels may have intensified, as the less educated were more vulnerable to unemployment than the better educated (Coile and Levine 2011). The effects of the recession by race/ethnicity are more difficult to gauge. First, as the literature on the recession has uncovered gender differences in the impact of the recession by race/ethnicity, it is clear that different variables cannot simply be added together (also see Browne and Misra 2003). For example, it appears that male Hispanics were hit hard by the recession, while female Hispanics were affected little (Engemann and Wall 2009). Second, most previous studies on WLE focused on the differences between whites and non-whites, while disregarding the heterogeneity of minority groups. An exception is the study by Hayward et al. (1996), who found that white males have a higher WLE than black males. Since it appears that whites were less affected by the recession than blacks (Engemann and Wall 2009), WLE might have decreased less for whites, potentially making the gap in WLE bigger.

To the best of our knowledge, no previous study has analyzed WLE by education within racial/ethnic groups. The results of prior research suggest that the educational gradient in mortality within working ages (Jemal et al. 2008) and older ages (Meara et al. 2008) is strongly dependent on the racial/ethnic group analyzed, with African-American men having the steepest mortality gradient, and Hispanic men and women having a

relatively flat mortality gradient. The association between education and the probability of being employed has also been shown to vary greatly by race/ethnicity. For example, the employment rate gradient by education has been found to be steepest among blacks and flattest among Hispanics (Bureau of Labor Statistics 2015). These findings suggest that the educational differences in WLE differ markedly by racial/ethnic or ethnic group. How this intersection of education and race/ethnicity was affected by the recession is hard to assess, especially given its differential impact by gender and by race/ethnicity.

Data and methods

Data

The Health and Retirement Study (HRS) is a panel study that has been running since 1992, and that focuses on Americans over the age of 50 (Juster and Suzman 1995). The survey is conducted by the Survey Research Center of the Institute for Social Research of the University of Michigan, and is supported by the National Institute on Aging and the Social Security Administration.

The interviews are conducted approximately every two years. In the interviews, several questions capture the labor force state at the time of the interview. Moreover, retrospective questions cover the time between two consecutive interviews. The year of death is obtained from either interviews with relatives or from the National Death Index. In addition to respondents aged 50 and older their spouses and partners are also interviewed. We included them in our analyses if they were aged 50 or older.

We measure employment based on self-reported labor force state. We distinguish between three different states: “employed”, “retired”, and “out of the labor force (but not retired) or unemployed”. Respondents who report that they are working or are on leave (e.g., sick leave) are classified as employed. Respondents who report either that they are retired, or that they are out of the labor force or unemployed and are over age 70 are classified as retired. The latter case does not occur often, as after age 70 few respondents reports being out of the labor force or being unemployed. Similar to Warner et al. (2010), we classify individuals who reported to be disabled as retired when they reach full retirement age, which depends on the birth cohort. Finally, the last category of unemployed or out of the labor force is comprised of non-retired individuals younger than age 70 or full retirement age who report that they are unemployed, disabled, a homemaker, or doing something other than working. While this last group is heterogeneous, this diversity is acceptable as our focus is on WLE.

We construct a working history for each respondent, focusing on annual transitions. To achieve this, we exploit the fact that labor force state is recorded to the nearest month. We use the state in the month of December to define the individual’s labor force state. For example, if a respondent was employed in December 1996 and retired in December 1997, we use the state employed for 1996 and the state retired for 1997. A detailed description of the constructed working histories is given in Dudel (2016).

Race/ethnicity is assigned based on two questions. All respondents who identify as Hispanic are classified accordingly. Respondents who do not identify as Hispanic are assigned a race/ethnicity based on another set of questions in which they are asked whether they primarily identify as white, black, American Indian/Alaskan Native, Asian/Pacific Islander, or something else. The latter three groups are subsumed in the category “other”.

As the number of respondents in this category is rather small, no analysis was conducted for this group. Educational status is measured using the highest degree the respondent ever obtained and is broken down into the following categories: no degree, i.e. some high school but no degree or less education; a high school diploma or GED; and a college or university degree. This roughly corresponds to the educational levels analyzed by Skoog and Ciecka (2001) and Krueger (2004), except that we do not further break down college/university education, as this is a relatively small group in the cohorts we consider.

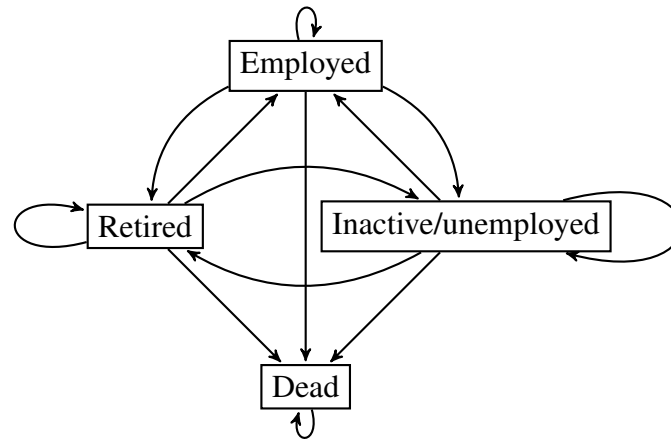

Modeling approach

We use Markov models to model the transitions between labor force states (Hoem 1977; Skoog and Ciecka 2010). The starting point is transition probabilities $p(i|x, j)$, which give the probability that an individual aged x and in labor state j will be in state i at age $x + 1$. Our state space consists of the transient labor force states “employed”, “retired”, and “out of the labor force or unemployed”; and of the absorbing state “dead”. The starting age is 50 and the maximum age is age 99, whereby those individuals who are still alive die with a probability of one. We assume for individuals aged 70 and older that they are either employed or retired, and that the state “out of the labor force or unemployed” is no longer relevant. Figure 1 depicts the state space ignoring age.

Transition probabilities are used to construct period working life tables, assuming that transitions occur mid-interval. Period working life tables are calculated for the years 1993-1997, 1998-2002, 2003-2007, and 2008-2011. For each period the results are derived differentiated by gender; by gender and race/ethnicity; by gender and education; and by gender, race/ethnicity, and education jointly. We use weighting to obtain working life expectancies without conditioning on the initial state. More formally, if $WLE(x, j)$ denotes the WLE for individuals aged x and in state j , the WLE by age, $WLE(x)$, can be calculated as $WLE(x) = \sum_j WLE(x, j)w_j(x)$, where $w_j(x)$ denotes some weight for age x and state j . We use weights for age 50 only, and otherwise report the results by age and state otherwise. Weights $w_j(50)$ were calculated from the empirical distribution of labor force states at ages 45-54 in all years by gender; gender and race/ethnicity; gender and education; or gender, race/ethnicity, and education. We combined the ages 45-54 and all years to increase the sample size for the initial distributions. The weights are time-constant so that differences between results by period are not due to differences in the distribution of states.

Estimation of transition probabilities

To estimate transition probabilities, we use multinomial logistic regression (Allison 1982; Greene 2012). This entails estimation of three logistic regression equations: one for survival, one for transitions to inactivity, and one for transitions to retirement (see appendix for coefficients). As transition probabilities sum to one no regression for transitions to employment needs to be estimated. Taken together the three regressions essentially model the state at time $t + 1$ as the dependent variable. We use the state at time t as one of the explanatory variables, as well as age recorded to the nearest month, which comes close to exact age. Age is modeled using a smoothing spline (Yee and Wild 1996; Debón et al. 2006). In addition, dummies were included to capture discontinuities in the age schedules (Behagel and Blau 2012): two dummies were used to capture peaks in retirement at ages 65

(a) State space for ages 50 to 69

(b) State space for ages 70+

Fig. 1 State space of the Markov model for ages 50 to 69 (upper figure) and state space of the Markov model for ages 70+ (lower figure).

and 66, respectively; another dummy covers ages 62 to 64, and a fourth dummy covers ages of 67 and above. Education was used as an explanatory variable as well as interactions of education and period. Estimates by gender and by gender and race/ethnicity are achieved by stratifying the sample into subsamples; e.g., Hispanic females. This also introduces implicit interactions of gender and race/ethnicity with all other variables.

The HRS includes the states of respondents in each December from 1992 to 2011. As the HRS interviews are usually conducted midyear, the state in December 2012 is not observed for most observations, and is thus dropped from the analysis. December 1992-December 1996 is used as the reference period, and corresponds to transitions in the 1993-1997 period. Three dummy variables were included that correspond to the 1998-2002, 2003-2007, and 2008-2011 periods, respectively. The 1998-2002 period includes the 2001 recession (Hall 2007), while the 2008-2011 period covers the most recent recession. This period starts with December 2007, which is usually seen as marking the beginning of the recession (Goodman and Mance 2011).

Correction of mortality estimates

In some cases, the survival probabilities estimated using the HRS are higher than those in the vital statistics. For example, for 2008-2011 the unadjusted (period) life expectancy of women aged 50 is 34.3 years, while the equivalent figure for 2010 reported by the Centers for Disease Control (CDC) is 33.2 years (Arias 2014). Although the direction of the difference is not unexpected, because poor health status may correlate with non-response, earlier studies using the HRS reported smaller differences (< 1 year; e.g., Warner et al. 2010). The larger difference we find can be attributed to the annual data set we use, while data collection is approximately biennial. For example, assume that a respondent reported being retired in July 1998 at the time of interview and died in March 2000 before giving another interview. Because of this, the labor force states in December 1998 and December 1999 are not known, while the state in December 2000 is “dead”. In this example, the transition to death can not be included in the estimation of transition probabilities, as the state before death and thus one of the explanatory variables in the multinomial logistic regression is unknown. In many cases the missing labor force states can be recovered from exit interviews, in which relatives give information on the time before death since the last interview, but these interviews are not always possible or complete. As the magnitude of the gap between our life expectancy estimates and CDC life tables is non-negligible, we had to correct it before we could make population-level estimates of WLE. We did this by matching the survival probabilities of our period working life tables with the CDC period life tables. Note that this adjustment affects our estimates of WLE only slightly, but makes a relatively big difference for WLE relative to life expectancy.

Using external data on survival is common in the construction of period working life tables (Smith 1986; Skoog and Ciecka 2010). In contrast to earlier studies, in which it was assumed that survival does not vary by labor force state or education, we match life expectancy by gender and race/ethnicity with CDC life tables, while allowing for variation by education and labor force state. The basic idea of the approach is that if survival probabilities by age, gender, and race are averaged over all labor force states and potentially educational level they should equal survival probabilities obtained from the CDC. To achieve this, we first calculated these averages and compared them to the CDC life tables. These comparisons are used to calculate scaling factors, which are used to increase or decrease the survival estimates obtained from the HRS. A detailed explanation is given in the supplementary materials.

This procedure was applied to all working life tables. Fig. 2 illustrates the educational gradient in survival for the period 2008-2011, obtained using the full HRS sample and after matching. Higher education is found to be associated with longer life among both men and women, with the exception of males in their early to mid-sixties, for whom our results show no educational differences. This is caused by our mortality correction algorithm (see supplementary materials). As mortality for these ages is low, it does not affect our main findings. Supplementary materials table B8 shows the racial/ethnic survival gradient by level of education and over time. The results are consistent with those of prior literature, which showed that there are racial/ethnic differences at each educational level, and that survival is improving for all groups except for whites with low education (Brown et al. 2012; HENDI 2015; Sasson 2016).

Fig. 2 Life table survivor functions by education and gender, 2008-2011. Source: Own calculations based on the Health and Retirement Study, years 1992-2012.

Weighting and resampling

For all calculations we use the survey weights of the HRS at the respondent level, including spouses and partners (HRS 2001). As weights are only provided for survey years and not for the years between surveys, we use weights of survey year t for year $t + 1$ as well. For respondents who died we used the weight of the last wave the respondent was interviewed, as the weights supplied in the HRS are zero for dead respondents. To estimate confidence intervals, we use a bootstrap approach (Skoog and Ciecka 2004). We apply a bootstrap procedure suggested by Cameron and Trivedi (2005) and resample individual working life trajectories, mimicking the complex sampling process of the HRS and accounting for both the cohort structure and oversampling in the HRS. A total of 1,000 bootstrap replications are used to derive percentile bootstrap confidence intervals. Testing relies on 95% confidence intervals of differences.

Results

Transitions and transition probabilities

Table 1 describes the data. We use data on 30,254 respondents. The number of transitions is 287,632. Two-thirds of the respondents are white, 17% are black, and 9% are Hispanic.

As there are only 348 male and 412 female individuals falling in the category “Other”, no analyses were conducted for this group. Of the sample, roughly half have high school education, about one-quarter have college/university education, and another one-quarter have less than high school education. The distribution of the number of transitions by sex, race/ethnicity, and education closely matches the number of observations. The number of transitions by type of transitions shows that most of the time, people retain the labor force state they reported the previous year. When this state changes, the individuals who had had been employed or outside the labor force are most likely to retire (6% and 14% of the transitions, respectively), while those who had been retired are most likely to die (4%). Importantly, however, significant shares of the individuals who are retired or are outside of the labor force re-enter employment (2% and 10% of the transitions, respectively), which demonstrates that retirement is not a straightforward transition (for transitions by gender, race/ethnicity, and education see the supplementary materials).

Fig. 3 gives an overview of the age schedule of selected transition probabilities by gender for the recession period 2008-2011 (see supplementary materials for figures showing transition probabilities by period). Panel A shows that the probability of staying employed was declining with age. Up to age 60 leaving employment mostly meant either becoming inactive or unemployed. While older women had a lower level of labor force attachment than men and a higher probability of becoming inactive, their probability of becoming unemployed was lower than that of men during the Great Recession (Sahin et al. 2010), which may explain their lower levels of employment exits for this age group. Sharp declines in the probability of staying employed could be observed among individuals aged 61 to 67, with the sharpest drop occurring at age 64; thus, a high proportion of the individuals who were employed at age 64 were out of employment at age 65.

The high probability of exiting employment at age 64 was mirrored by the probability of transitioning to retirement (Panel B), which peaked at age 64.¹ This result is in line with that of previous studies, which found that it is still common for people to retire at age 65 (Coe et al. 2013; Behagel and Blau 2012). Among individuals above age 70 the probability of staying employed declined sharply, while the probability of retiring increased steadily. In both cases males exhibited higher labor force attachment than females.

Panel C shows that the probability of returning to employment after retiring, which was high among relatively young retirees (Cahill et al. 2011), but declined with age, with a sharp drop occurring at age 65. This may be because large numbers of people retire at age 65, and newly retired individuals seldom re-enter the work force immediately (Hayward et al. 1994).

Working life expectancy

Table 2 shows the WLE and the proportion of remaining life expectancy at age 50 that is spent working (relative WLE) by gender, race/ethnicity, and education. More detailed results, including estimates of remaining life expectancy are given in the supplementary materials. Fig. 4 and 5 illustrate the results by race/ethnicity (Fig. 4) and education (Fig. 5).

In 1993-1997, the average WLE was 14.5 years for men and 11.4 years for women. These figures represent 54.1% and 36.5% of the total remaining life expectancy. WLE

¹The probability of retiring was calculated by averaging the probabilities for employed individuals and individuals out of the labor force using weights, as described in the previous section.

Table 1: Number of observations and transitions by race/ethnicity and gender, education and gender, and by type of transition.

		Respondents	%	Transitions	%
Male	White	9,632	32	94,949	33

fluctuated for both men and women over the observation period, decreasing by approximately one year in the period 1998-2002, then bouncing back in the 2003-07 period. In the 2008-2011 period, which captures the Great Recession, WLE for men decreased statistically significantly and fell below the levels observed in any other period, to 12.7 years; while WLE for women declined less sharply and not statistically significantly, to 10.9 years. As total life expectancy increases for both men and women, the fraction of remaining life at age 50 that is spent working can decline without a proportional increase in WLE. Indeed, the fraction of remaining years spent working at age 50 decreased between 1993-1997 and 2008-2011 from 54.1% to 42.9% for men, and from 36.5% to 33.0% for women. The smaller decline for women may be attributed to the fact that the recession had a smaller impact on women than on men, and that remaining life expectancy at age 50 increased at a slower pace for females than for males. These patterns are similar for most educational and racial/ethnic groups, albeit at different levels.

Working life expectancy by race/ethnicity and gender

Looking at Fig. 4, it is clear that there are marked racial/ethnic differences in WLE. An overview of which comparisons are statistically significant at the 5% level is given in table 3. White males have the highest WLE across all observation periods, while Hispanic

females have the lowest WLE in most periods.² The difference in WLE between these two groups is up to 6.9 years, while the largest difference between white males and females is considerably smaller, at about 3.4 years. Black males and females have a low WLE, but the gender differences among blacks are not as strong as they are among whites and Hispanics, and – unlike among whites and Hispanics – the gender differences are not statistically significant. WLE is also significantly higher for white males than for black males. A similar pattern emerges for the differences between white males and Hispanic males, except for the period of 1998-2002. The differences in the level of WLE by race/ethnicity are always significant for females. Controlling for education in addition to race/ethnicity this is not the case, though (see below).

For both white males and females there is no clear trend in WLE, and the differences between years seem to be mostly driven by period effects, which affect both males and females. The decreases from 1993-1997 to 1998-2002, and in particular from 2003-2007 to 2008-2011, were smaller for females than for males (–0.7 for females vs. –1.6 for males). These results are in line with findings that show that the recessions in 2001 and 2007-2009 had a more severe impact on males than on females (Wood 2014).

While the results for blacks show patterns of increase and decrease similar to those of whites, the results for Hispanics show very different patterns. For Hispanic males, WLE increased 0.3 years between 1993-1997 and 1998-2002 and 0.3 years between 1998-2002 and 2003-2007, while WLE decreased statistically significantly by 2.4 years between 2003-2007 and 2008-2011. For Hispanic women, by contrast, WLE increased 1.4 years between 2003-2007 and 2008-2011, even as it decreased for all other groups. Moreover, the gender differences in WLE between 2003-2007 and 2008-2011 were statistically significant for Hispanics, but not for whites and blacks. These results are consistent with the findings of Engemann and Wall (2009), who argued that the gender differences in the effects of the Great Recession have been more pronounced among Hispanics, and that female Hispanics were not strongly affected.

²Results for Hispanics may be influenced by selective migration, as individuals in poor health have a higher probability of returning to their country of origin than those in good health (Turra and Elo 2008).

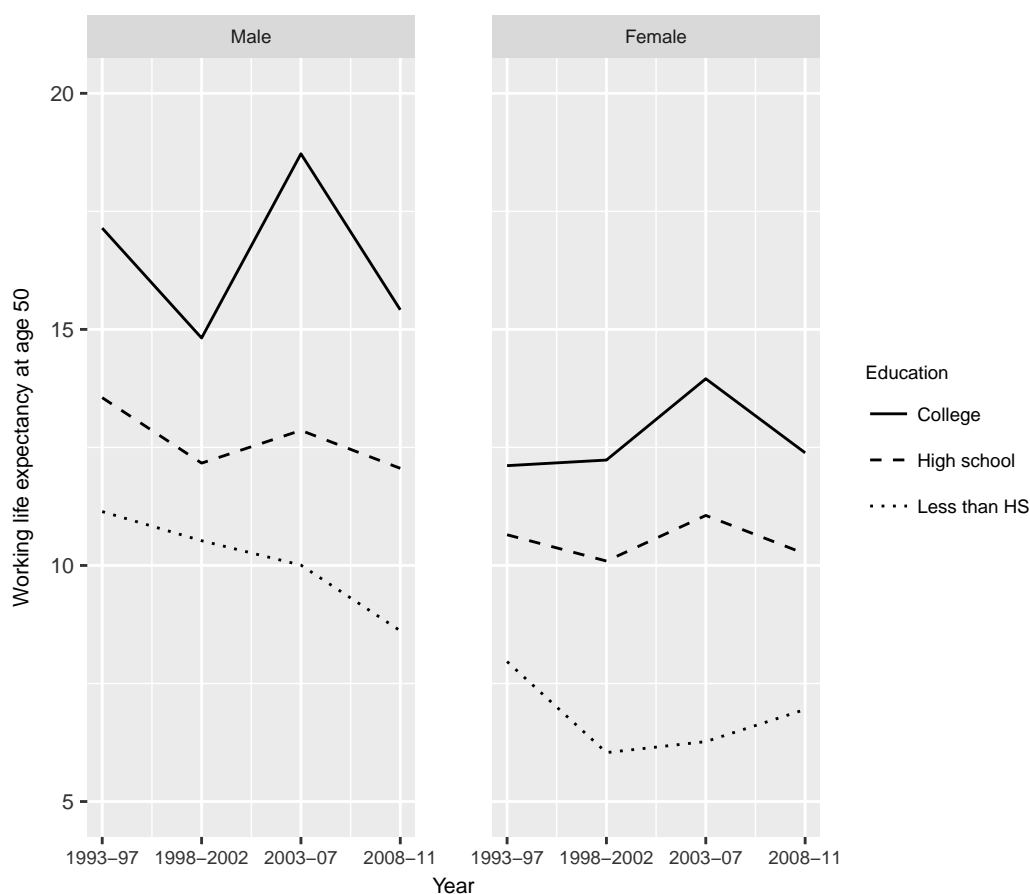

Fig. 5 Working life expectancy at age 50 by education and gender. Source: Own calculations based on the Health and Retirement Study, years 1992-2012.

Working life expectancy by education and gender

Fig. 5 shows that there is a clear educational gradient in WLE, whereby individuals with a college or university degree have the highest WLE, while those with less than a high school degree have the lowest WLE. All of these differences are statistically significant at the 5% level. For each educational level, males have a higher WLE than females. Most of these differences are statistically significant, except for the period of 2008-2011, during which the gender gap was not significant for individuals with less than a high school degree. Apart from these similarities, we see marked differences between educational groups. While the gender gap in WLE has been closing for both individuals with high school education and individuals with less than a high school degree, it has been highly volatile for individuals with a college/university degree.

Over the study period, WLE was volatile among individuals with college/university education, especially among males. For example, the WLE of males with a college degree increased 3.9 years between 1998-2002 and 2003-2007, and decreased 3.3 years thereafter; both changes are statistically significant. The changes were less pronounced for females with college education, a finding that further confirms the assumption that females have been less affected by the Great Recession than males (Wood 2014).

The changes in WLE among males and females with high school education roughly matched those among individuals with a college/university degree, but the fluctuations

were not as pronounced. For instance, among males with high school degree WLE declined just 0.8 years between 2003-2007 and 2008-2011. While WLE among males with less than a high school degree decreased steadily, the difference between 2003-2007 and 2008-2011 amounted to 1.4 years, and was thus considerably smaller than the decline among males with college education. WLE among females with less than a high school degree actually increased 0.7 years during this period. This result is quite remarkable, as there is a general consensus that individuals with low levels of education have been more affected by the recent recession than others (Engemann and Wall 2009; Coile and Levine 2011). A potential explanation for this finding is the added worker effect: women with less than a high school degree may have (re-)joined the labor force to compensate for the job loss of a partner. Moreover, they may compensate for reductions in working hours and wages, which declined during the recession (OECD 2010).

Working life expectancy by race/ethnicity, gender, and education

The results that combine all three variables under study partly mirror the findings already discussed above. When interpreting results one has to keep in mind that some groups are rather small. This holds especially for black males with college/university degree, male and female Hispanics with college/university degree, and male Hispanics with high school degree, with sample sizes of 273 individuals, 136 individuals, 154 individuals, and 413 individuals, respectively. All other groups have sample sizes of more than 500 individuals.

Generally, whites had a higher WLE than blacks and Hispanics, and WLE increased with educational attainment. However, there were also important differences in WLE by race/ethnicity and gender when conditioned on education (table 4). For white and Hispanic males, the differences were of mixed signs and magnitudes. At the beginning of the observation period, there were relatively large differences between white and black males, with white males having a higher WLE at all educational levels; but by 2008-2011, the differences between white and black males with college and less than high school education had disappeared. The differences in WLE between whites and Hispanics also disappeared during the observation period. But because the sample size of blacks with a college degree is rather small, the results for this educational level should be viewed with care.

White females had a higher WLE than black or Hispanic females, irrespective of educational level or year; although the differences were often small and not significant, especially for those with less than a college degree. These findings are line with the results of Millimet et al. (2003, table 5), which indicated that the differences between white and non-white women aged 50 were negligible when controlling for educational attainment.

The differential contributions of mortality and employment to differences in WLE

Differences in WLE are driven by differentials in the likelihood of being and staying employed if alive, and in the probability of being alive. For some comparisons, the differentials in mortality and in the probability of being employed reinforce each other; whereas for other comparisons, they may work in the opposite direction. We therefore analyze for selected key contrasts to what extent the observed differences are attributable to probabilities of employment, and to what extent they are attributable to mortality rates. In

Table 4: Differences in WLE by educational attainment by gender and race/ethnicity. Differences which are statistically significant at the 5% level are marked with an asterisk.

this analysis we focus on the 2008-2011 period and on comparisons across sub-populations, because within-population trends are almost exclusively driven by changes in labor force participation patterns, not by changes in mortality.

A description of the methodology and detailed results are given in the supplementary materials, and we only summarize these findings here. In case of gender gaps by race/ethnicity we find that the effects of higher life expectancy for females and higher employment rates for males cancel each other out to some degree for blacks and Hispanics. In contrast, for whites the gender gap in WLE can be explained to a large degree with employment. Racial/ethnic differences by gender and educational differences by gender are also both strongly driven by differential employment rates. In case of the former the contribution of mortality is low, and for Hispanics actually lowering the difference to whites. For the latter the contribution of mortality is larger in absolute terms, but still considerably smaller than the contribution of employment and only explaining a small proportion of the differences (approx. 20%).

Discussion

Main findings

Although working life expectancy (WLE) was rather volatile over the study period, our results suggest that the Great Recession has had a negative impact on the WLE of older males, and to a lesser extent on the WLE of females. But despite 1-2 year declines in WLE, American men who have reached age 50 still spend 13 years, or more than two-fifths of their remaining life, working; and 50-year-old American women work 11 years, or one-third, of their remaining life. Compared to the pre-recession period the gender gap in WLE has dropped from three to two years, in line with earlier analyses suggesting that women were less affected by the recession than men (Engemann and Wall 2009). While

adverse labor market conditions seem to have outweighed the incentives to stay in the labor force longer for the US population as a whole, our findings also show that there is considerable heterogeneity across sub-populations, both in trends and levels of WLE.

We found that variation in WLE by racial/ethnic groups is large. Over the 20-year observation period from 1992 to 2012, the WLE of men at age 50 was consistently between four and five years lower among blacks than among non-Hispanic whites and this gap did not increase during the recession. Even though the gap did not increase, the recession hit black males harder than whites in relative terms, with decreases in WLE between 2003-2007 and 2008-2011 of 16% and 11%, respectively, in line with Engemann and Wall (2009) reporting that whites were affected less than blacks. Among Hispanics, WLE was in between the WLE values of the other two groups. Among women, however, blacks had a WLE that was only around two years lower than that of non-Hispanic whites. In the 15 years prior to the Great Recession, from 1992 to 2007, black women also had higher WLE levels than Hispanic women. However, this differential was reversed in 2008-2011, as Hispanic women caught up with black women.

Racial/ethnic differentials in WLE are mostly due to differences in transition probabilities (staying employed, returning to the labor market, retiring, etc.). The differences between blacks and whites might be explained by the relative disadvantages of blacks and discrimination against blacks in the labor market (Altonji and Blank 1999; Pager 2009). Moreover, blacks are, on average, less healthy, and have a higher risk of being disabled than whites, which is reflected in a lower active life expectancy (Hayward and Heron 1999). The finding that Hispanics have a lower WLE than non-Hispanic whites cannot be explained by health, as Hispanics compare favorably to blacks and whites in terms of both health and life expectancy (Lariscy et al. 2015). Indeed, our decompositions suggest that mortality contributes negatively to – i.e., narrows – WLE differences between whites and Hispanics, and that the WLE differential is fully explained by lower levels of labor market attachment among the Hispanic population.

Of the groups studied, the Great Recession had the strongest negative impact on WLE among male Hispanics, while Hispanic females experienced an increase in WLE in 2008-2011. This differential impact by sex among Hispanics is consistent with the findings of early analyses by Engemann and Wall (2009), which indicated that the decline in employment has been particularly small among Hispanic women. It is possible that as the labor force participation of female Hispanics had been relatively low, there was a large potential for the added worker effect, whereby inactive individuals enter the labor market when their partner becomes unemployed (Starr 2014).

Educational differences in WLE were found to be large and persistent. Among men in 2008-2011, those with college/university education could expect to have 16 more working years, while those with less than high school education could expect to have only eight years. Among women the differential was similar, from 14 to six years. The direction of the differential is not surprising given the well-known educational differences in labor market opportunities, health (Crimmins and Saito 2001; Dupre 2008), and life expectancy (Montez et al. 2011; Olshansky et al. 2012). However, our decompositions show that mortality contributes relatively little (less than 20%) to the educational differences in WLE, and that the remainder of the differences are attributable to weaker labor force attachment among the less educated.

We found a strong negative impact of the Great Recession on WLE for those with college/university education. This result is unexpected, as the lesser educated are generally

considered to have been hit harder by the recession than the better educated (Engemann and Wall 2009), but may be due to the fact that these individuals have a higher probability of retiring if they become unemployed than other groups, possibly because they can more easily afford leave the labor force (Rutledge 2015). Indeed, additional calculations show that the probability that a 50-year-old employed male would be retired at age 65 increased considerably for males with a college/university degree: conditional on surviving, the probability was 27% in 2003-2007, while it was 37% in 2008-2011. For males with a high school degree and no degree, the probability increased by one percentage point and four percentage points, respectively. For women, the differentials were qualitatively similar, with the differences between 2008-2011 and 2003-2007 amounting to 7% (college/university), 5% (high school/GED), and 6% (less than high school).

Our findings are largely consistent with earlier findings on WLE in the US. Smith (1986) estimated the WLE at age 50 to be 12.3 years for men and 9.8 years for women in the 1979-1980 period. This estimate for women is lower than our estimates, which are between 10.7 and 11.6 years, but the Smith paper covers an earlier period in which female labor force participation was lower. The findings of Millimet et al. (2003, 2010), which cover the period from 1992 to 2000, are qualitatively similar with respect to the differences between groups. For instance, they found that non-whites males had a lower WLE than white males, while the differences between white and non-white females were small. Skoog and Ciecka (2002) estimated WLE at age 50 to be 13.1 years for men in 1997-98, while Warner et al. (2010) report an estimate of 13.8 years for the period from 1992 to 2004 using HRS data. If we restrict our analysis to the period from 1992 to 2004 and do not control for year, we get a WLE estimate of 13.4 years for males. The small difference is most probably due to different definitions of WLE; while we focus on employment, the estimate of Warner et al. (2010) covers both time spent in employment and unemployment. Moreover, Warner et al. (2010) used biennial data, while we employed annual data, which also could cause small differences (Wolf and Gill 2009).

It is worth noting that although the variation in WLE by level of education and race is very large in the US, even the sub-populations with low working life expectancies tend to have higher WLEs than people in the UK (Butt et al. 2008), Spain (Dudel et al. 2016), and Finland (Leinonen et al. 2016). For example, in 2012 in Finland, male WLE at age 50 was 9.1 years (Leinonen et al. 2016). White, black, and Hispanic men in the US in 2008-2011 all had a WLE of at least 9.1 years. Across educational groups, only those individuals with less than high school education had less than 9.1 years of WLE. For women, WLE among sub-populations, as defined by race, was close to the Finnish average of 10 years (Leinonen et al. 2016). Females with high school education also had a WLE close to Finnish females, while females without a degree and females with a college/university degree, respectively, were three years below and two years above female Finns.

Methodological considerations

When interpreting our results it is important to acknowledge the period perspective we employ. It allows us to assess the impact of the recession by showing how individuals above age 50 would fare if transition probabilities remained constant; i.e., if the conditions of the recession prevailed over a period spanning old age. Our findings are not directly comparable to those of cohort studies, though.

Several other studies focusing on WLE do define it in terms of labor force activity

(e.g., Millimet et al. 2003; Skoog and Ciecka 2010; Warner et al. 2010), i.e., covering both employment and unemployment, while we focus on employment only. This different definition of the state space hampers the comparability of findings, but only to a small degree. If we combine employment and unemployment in one state, our estimates of WLE on average increase by roughly 0.5 years. For instance, WLE including both employment and unemployment for males with college/university education amounts to 13.3 years (1995), 12.5 years (2000), 13.3 years (2005), and 12.6 years (2010), while if we only include employment these numbers are 13.3, 12.2, 12.8, and 12.0 years, respectively.

A potential limitation of our analysis is bias due to panel attrition. While we adjust our estimates of transition probabilities to match CDC life tables, this can be expected to solve this issue only partly. For instance, assume that individuals who were employed at time t and who are not in the survey anymore at time $t + 1$ have a higher probability of retiring than those who remain in the panel. This would lead to under-estimation of the probability of retiring and would bias estimates of WLE upwards. To assess how panel attrition might affect our results, we conducted the following experiments: For those transition for which the state at time t is known but not at $t + 1$, the state at $t + 1$ was set to “employed” if the individual was below 75 age, and to retired otherwise. In a second experiment, the state at $t + 1$ was set to “out of the labor force or unemployed” if the individual was below age 75, and to retired otherwise. In the first experiment WLE of males and females is up to 1.5 years higher; in the second experiment it is up to 1.5 years lower. These differences are not small, but they are based on rather extreme assumptions. Furthermore, in both experiments trends and differences between males and females remain mostly unchanged. This suggests that panel attrition can be expected to mainly bias the level of our estimates. For differences over time or between groups to be biased would require rather strong selection in different directions.

We assessed the impact of the Great Recession by analyzing the differential levels in WLE before and after it. However, changes in WLE may be caused not only by the crisis, but by other factors as well, such as policy changes or pre-existing trends in WLE. Both the heterogeneity of WLE across sub-populations and the variability of WLE over time point in this direction. While we cannot rule out other factors, the crisis can be seen as an exogenous shock, and it seems unlikely that other factors contributed substantially to the key patterns we observed, such as the increase in WLE among female Hispanics and the decrease in WLE among male Hispanics, which are consistent with other findings from the literature. It remains to be seen how persistent the effect of the crisis will be, and WLE might have recovered to pre-recession levels after the period we study.

There are further limitations to our analysis. First, our results are for individuals at age 50, and may not give a complete picture of WLE over the whole life course. For example, differentials in WLE by education might be different at age 20 than at age 50. Second, our analyses ignore working hours and wages. Accounting for working hours, e.g., differentiating between full-time and part-time employment (Krueger et al. 2006), could potentially change our results but would also increase the size of the state space. Third, our results by gender, race/ethnicity, and education are in some cases based on rather small sample sizes, making some of our findings difficult to interpret. Small sample size also limits the number of covariates and interaction terms we can include when estimating transition probabilities. Fourth, we assign labor force states based on self-reported labor force state, similar to, e.g., Warner et al. (2010). This circumvents the problem of deciding when an individual is, for instance, retired based on other indicators,

which is more complicated than it may seem at first sight (Denton and Spencer 2009). Still, using other indicators could lead to different results.

Conclusion

Using data from the US Health and Retirement Study, we constructed period working life tables by gender, race/ethnicity, and education; and analyzed the impact of the Great Recession. We found strong differences by gender, race/ethnicity, and education. These differences were mostly driven by differences in transitions between labor force state, and not by differences in mortality. At age 50, men had a remaining working life expectancy (WLE) that was approximately two years longer than that of women. Individuals with college/university education could expect to work more than two times longer than those with less than high school education, and non-Hispanic whites could expect to work more than one-third longer than blacks. However, these differences mostly disappeared if education was controlled for, with the exception of differences between white and black males. This may be due to small sample size for some groups like, e.g., black males with college degree, though. Gender gaps varied strongly by race. For example, except during the Great Recession, the gap between males and females was largest among Hispanics; whereas the gender differences were small among blacks.

Our findings point to the importance of gender and racial differences, the intersection of these differences, economic conditions, and the interaction of all of these factors in determining the length of working life. Trends over time show no clear expansion of working life. If the shares of the US population who earn a high school or a college or university degree continue to grow (Ryan and Bauman 2016), average WLE may increase; however, this effect may be at least partially offset by later entry into the labor market. A concern is the heterogeneity of WLE in general and the consistently low WLE of some groups, particularly blacks and individuals with less than high school education. Policies that better address this heterogeneity may be needed. Moreover, a better understanding of how differences are shaped by inequalities in health, health behaviors, and disability is needed to design effective policies that encourage a productive prolongation of working life, without an accompanying compromise in well-being.
